The surgical management of this type of wound was similar to that described under primary débridement. Success depended upon total wound excision and thorough débridement of the brain track. A dural graft was not used. The local instillation of penicillin for several days post-operatively in conjunction with its systemic use, aided in wound healing. Terian (Rumanian) (188) reported experiences with delayed operations. In 71 per cent of 103 cases, operation was undertaken within 20 days after injury usually on the sixth to eighth day. Eight of the patients died; 6 of these had meningitis at the time of operation. The fatality rate of 183 cases without meningitis was 1:1 per cent. The conclusion was made that "the time interval after wounding is less important in cranio-cerebral injuries than meticulous and specialized care in investigation, operation and after treatment." The dura was not closed in any of these cases and the scalp edges only

were apposed over the wounded brain by a few sutures.

Delayed primary débridement of cranio-cerebral wounds differs from earlier recommendations made at the start of World War II. Hottel (101) stated that after from 24 to 48 hours "the whole wound should be packed widely open under vaselined gauze or rubberized tissue and the resulting fungus allowed to heal by granulation and recede." Schnitz and Bettsdahl (173) also suggested that after 48 hours the penetrating wounds should be treated as a brain abscess with "open drainage."

SECONDARY DÉBRIDEMENT (10-30 DAYS)

Healed wounds presenting retained bone fragments within the brain were frequently encountered [Italy, 13.4% France, 31.9% (210)]. These were usually the result of necessary haste due to lack of time at the primary débridement when the "all or nothing" rule was not followed. By means of roentgen studies the fragments were accurately localized and after evening of the bone defect a conservative secondary track exploration with removal of the bone chips was performed. This policy has been followed by Eden (58) Schwartz (174) Schornstein (171) and Rowe and Turner (165). When necessary a dural graft was applied with safety since the wound was not grossly contaminated as in patients requiring late primary débridement. The scalp was closed. Tonnies (191) reported that all cases which had been provisionally operated on for tangential wounds of the brain showed prolapse, with splinters of bone in the depths of the brain. The prolapse was reduced by repeated lumbar punctures. Under local anesthesia, the opening in the skull was then enlarged; the depths of the wound freed from dead matter, and any remaining splinters of bone exposed and withdrawn. The wound was kept open by a Mikulicz tampon soaked in protosol, to assure the free escape of discharge. It was noticed in the wounds which had not been tampered with at the front that prolapse of the brain had been hindered by the splinters of skull left in place. At both the primary and the secondary débridements, the attempt was made to remove completely all organic material, consisting mainly of bone chips and of the inorganic material when possible.

In general, the management of retained metallic fragments followed the principles set forth by Frazer (137). Some (67-210) have reported that ragged metallic fragments were found to be laden with organic material—tiny bone fragments, hair and helmet lining—and cultures of such

missiles, as well as of bone fragments usually resulted in the growth of pathogenic organisms. Not only the size of the metallic foreign body but the irregularity was of importance. It is reasonable to view the presence of retained shell fragments particularly as a threat to a future inflammatory complication. Such findings usually do not occur when the penetrating missile is a smooth intact bullet.

CONSIDERATION OF BRAIN ABSCESS

The term brain abscess, as used in this article describes a purulent collection or collections within the brain substance which followed track injury produced by a penetrating missile. An incidence of 16 per cent occurred among 206 patients (including German prisoners of war) with penetrating wounds of the dura and brain observed by Webster Schneider and Lofstrom (210). The incidence among American wounded was 14 per cent in Italy and 19 per cent in France (210). Cairns (27) has reported an incidence of abscess formation in 25 per cent of patients in whom wound débridement was incomplete or performed late. A similar proportion was estimated by Rowe and Turner (165). In Ascroft's series (25) 75 of 292 patients developed brain abscesses under his care. Eden (25) however had but 1 case attributed to the fact that cases were received at an earlier stage and before they had been operated on by the general surgeon.

No case of abscess was noted among patients in whom the dura was not penetrated (210). The abscesses occurred early and were associated with wound infections and frequently with hernias or fungi. Usually they were not encapsulated but were localized by reactive inflammatory tissue of a dense quality at the site of the original débridement and also in the track produced by the missile or the bone fragments. Kornean, Ky (114) noted that in 69 per cent of cases brain abscesses "were due to an infection of the wound. In 28 per cent they were cortical and in 53 per cent intracerebral. They occurred 2 or 3 weeks after injury.

Several surgical methods of management have been employed in treating this type of complication (210). The techniques were based primarily upon a complete redébridement of the wound and the abscess by means of excision of all inflammatory tissue and the abscess itself, the latter being removed by suction. The resulting wound was then treated by (1) closure of the scalp, (2) closure of the scalp about a tube for the instillation of penicillin, (3) exteriorization of the cavity (21) and (4) exteriorization with a temporary dural graft (Fig. 3).

Fig. 4. This patient presented a brain abscess associated with a retained bone fragment and an infected wound. Management consisted of excision of the wound and the abscess followed by the daily instillation of penicillin solution through the scalp. Primary healing occurred.

Webster Schneider and Lofstrom (210) concluded that an early abscess following a penetrating wound of the brain must be treated by complete removal and not by drainage without excision (Schulze and Betzendahl [1-3] in 1940 recommended simple open drainage) and further that no single technique was applicable to all situations. There were situations in which it was possible to close tightly the overlying scalp after wound excision and extirpation of the abscess (174). This is a technique similar to that used for late purulent and nonpurulent undébrided wounds which has been successfully practiced with or without the local use of penicillin. Drainage of the abscess followed by the local instillation of penicillin through a small rubber tube placed into the cavity has been employed by Eden and Cairns (25) and Howe and Turner (165). The latter use a technique of complete evacuation of the abscess and the removal of all foreign bodies establishing drainage by use of a Penrose sheath or rubber tissue drain or occasionally a soft rubber

tube. In addition, a Dakin tube is introduced into the depths of the cavity. At this time a mixture of dry penicillin and sulfanilamide is placed in the cavity. In contradistinction to the ordinary practice of leaving the wound entirely unsutured, it has been found feasible, with the aid of chemotherapy, to carry out a nearly complete closure in many cases. Webster Schneider and Lofstrom (210) found it difficult either to aspirate through a small rubber tube or to inject penicillin solution and were obliged to remove the tubes in 48 hours and inject the solution through the scalp (Fig 4).

In a number of instances these methods were not successful, namely when the frontal or mastoid sinuses were involved when the scalp was edematous and necrotic when there was a large scalp defect through loss of tissue when débridement of the abscess was not as complete as desired. A special form of management was then used which was as follows.

After the usual complete redébridement of the wound and excision of the abscess, the remaining cavity was covered temporarily by means of a graft of fascia lata sutured to the débrided dural edge. This temporary graft and the surrounding bone edge were covered with vaseline gauze, the scalp wound being left open. Penicillin solution could be injected daily through the graft into the site of the abscess. At the end of 15 days, the fascial graft was removed and the underlying brain was prepared for a split thickness graft, which was applied from 5 to 7 days later without disturbing the scalp. Any mobilization of the scalp was avoided in consideration of the subsequent cranioplasty which would also complete the scalp closure.

The temporary dural graft of fascia lata served two purposes: first, it prevented cerebral herniation, and second, it prevented cerebrospinal fluid leakage. Following the débridement of an abscess with disturbance of all the barriers to infection meningitis may result or diffuse infection may be present at the time of the attack upon the abscess. In either situation postoperative cerebral swelling, herniation and fungus formation may result if the débrided area of the abscess has been exteriorized without a covering. A pack or drains may be extruded. If the scalp has been closed over such a defect in the dura, there may be extrusion of the brain subcutaneously. The use of a fascial graft as a temporary covering prevents such herniation until the infection is brought under chemotherapeutic control. Leakage of cerebrospinal fluid into the frontal sinuses may also be controlled by the temporary graft, which

is removed when the brain has sealed itself about the line of normal dura. A temporary graft was used as it was held to be unwise to bury a fascial graft in an unclean wound because of the risk of necrosis of the graft and continued wound infection. However, Rowe and Turner (165) have successfully buried fascial grafts in unclean wounds.

Lebedenko (118) reported a mortality of 15 per cent in the treatment of 231 patients with brain abscess, and his notation concerning the technique of operation was that "if the walls of the abscess are intact, the abscess is removed in toto." (David and Ferey [47] found that 24 per cent of 83 patients with fungus died.) Kornevsky (114) reported a fatality rate of 18 per cent in surgically treated cases of brain abscess. Bukulov (Russian) (22) reported that 16.8 per cent of the patients with abscess died when treated at a specialized evacuation hospital. The mortality in Ascroft's cases was 25 per cent (25). Webster Schneider and Lofstrom (210) found that 27 per cent of the patients with abscesses treated by various methods died. The mortality among those treated by the use of a temporary dural graft (mainly frontal sinus wounds) was 18 per cent.

CONSIDERATION OF WOUND INFECTION FUNGUS, MENINGITIS

The occurrence of wound infection was observed to be dependent upon several factors. These included the season of the year and the associated weather conditions, the terrain on which the fighting took place, the mobility of the war, the speed of evacuation, the number, type, and severity of the casualties, the degree of blood loss, and the extent of the replacement. These influences, and probably many more such as the number of dressings and the exposure of the wounds, had a bearing on wound healing. It was of interest to compare the incidence of wound infection in patients in the Italian and French theaters with that in a group of German prisoners of war. A high incidence of wound infection occurred in the latter group when certain known factors included (1) late primary wound débridement and (2) inadequate or incomplete wound débridement. On a rapidly moving front under ideal weather conditions (late summer) the POW patients were treated by the same chemotherapeutic routine as wounded American soldiers. The comparative statistics were as shown in Table II (210).

The comparison warrants the conclusion that the prime factors in preventing infection are early and thorough wound excision. Cairns (27) found

Lack of retained bone fragments									

that in fresh cases operated on by neurosurgeons the incidence of postoperative intracranial infection was only 3.7 per cent. Rowe and Turner (1965) have reported that approximately 15 per cent of the head wounds showed some degree of infection. Slemon (1978) found an infection rate of 12.9 per cent. Plans for wound care must be designed to meet the complications arising from delayed and hasty débridements. The average time interval between wounding and operation was 27.6 hours (maximum 5 days—minimum 6 hours) in patients reported by Slemon (1978). The importance of wound infection to late sequelae has been shown by Ascroft (7).

Although fungus of the brain was a frequently encountered condition (210) this complication did not constitute the problem which it appeared to present in World War I. By means of chemotherapy a spreading encephalitis was controllable and fulminating cerebral swelling and extrusion of the cerebral tissue was prevented. The streptococcus organism responsible for rapid and fatal infections in World War I was particularly vulnerable to sulfonamide and penicillin therapy. Cairns (27) reported that the staphylococcus aureus is a frequent wound contaminant proved by the bacteriological examination of wounds during the Sicilian campaign. The Russians (25) found that only 2 of 300 head wounds were due to anaerobic pathogens (Report by a Committee of Soviet Scientists, 1943 [25]).

The principle of closing the dura following primary wound débridement prevented postoperative herniation. Instances of extrusion of the brain with a separated and infected wound were frequently the result of an underlying cerebral abscess. Relief was obtained after excision of the fungus and total débridement of the associated abscess usually pocketed under the extruded mass.

A meningitis which may have been present was usually completely controlled by means of continuously administered penicillin or sulfadiazine therapy. Exception to this occurred when the

invading organism was drug resistant, being then usually of a gram negative type (Friedlander's bacillus). An unsubiding meningeal infection was also found in the presence of a cerebral abscess which sustained it.

On failure of a patient to improve normally following primary débridement with clinical evidence of infection as the cause of the failure, three steps were taken: the chemotherapeutic program was revised to meet the new demands, efforts were directed at proving the presence of an abscess and cultures were made of the cerebrospinal fluid (210).

SULFONAMIDE AND PENICILLIN THERAPY AND BLOOD LOSS REPLACEMENT

Both sulfadiazine and penicillin were used in the treatment of the cases presented by Webster, Schneider and Lofstrom (210). Those patients who were observed in the Italian Theater were in the main treated with sulfadiazine, while those in the French Theater received penicillin. The incidence of wound infection in each series of cases did not vary significantly: being 19.8 per cent and 23.6 per cent respectively. Of the group of patients with cranial wounds complicated by brain abscesses, the first 15 were treated with sulfadiazine (penicillin being used only when sulfadiazine failed to control the infection). The latter 18 were, in general, treated with penicillin. An appraisal of the results (mortality) based upon the type of chemotherapy employed showed that in the group of 15 cases treated with sulfadiazine 4 deaths occurred. Penicillin also failed to control these fatal infections when used after the ineffectiveness of sulfadiazine was apparent. Among the

TABLE III THE RELATION BETWEEN EPILEPSY AND WOUND SEPSIS

	Number of Cases	Number with Fits	Per cent of Fits
Wound healed in 5 days	30	3	10
Wound healed in from 15 to 60 days	50	1	2
Wound unhealed after 60 days	28	10	35.7

18 patients who received penicillin 5 deaths resulted. Three of the 18 patients were given sulfadiazine treatment when the penicillin failed and all presented favorable outcomes. In this limited analysis, an outstanding difference in the effectiveness of these drugs did not seem to exist. Others have observed the superiority of penicillin (89). Slemon (178) observed an incidence of infection of 31.2 per cent in 32 patients treated by the local application of sulfathiazole while the rate decreased to 9.2 per cent in 184 cases treated locally with penicillin and a sulfadiazine drug. In both groups sulfadiazine was used systemically. Pilcher (154) in over 1,000 experiments has studied various aspects of the chemotherapy of intracranial infections. Among many observations, the following are the most significant:

1. Sulfathiazole may produce severe or even fatal convulsions when applied to the brain and should never be used. (Contrary to clinical experience of Cairns [25].)

2. Experimental staphylococcal meningitis was markedly benefited by oral sulfadiazine but not by oral sulfathiazole.

3. "Penicillin when given intravenously was ineffective in staphylococcal meningitis, but when given intrathecally it greatly reduced the mortality rate.

4. Penicillin given intrathecally in normal dogs produced variable degrees of mild irritation and pleocytosis in the cerebrospinal fluid, apparently dependent largely upon the amount of impurity in the preparation of penicillin.

5. "The healing of open cerebral wounds contaminated with staphylococcal organisms has been augmented by the local use of sulfadiazine but was apparently unaffected by local sulfathiazole or local penicillin. (Contrary to clinical observations.)

6. Chemotherapeutic agents given systemically have benefited experimental cerebral abscesses only in so far as associated meningitis, if present was benefited. In other words, our experiences indicate that such drugs probably do not gain access to well-encapsulated infection of the central nervous system.

The use of either drug it appears, is effective only in proportion to the thoroughness with which the source of the infection is irradiated by surgical measures.

Blood replacement must be recognized as an important factor contributing materially to the control of infection and the production of satisfactory wound healing. A lowered hemoglobin and hematocrit were frequently encountered in spite of previous transfusions in forward installa-

tions, particularly in patients with associated injuries. The latter occurred in 36 per cent of one group of patients with cranial wounds (136) and in 28 per cent in another series (27). Upon admission to the general hospital, liberal use was made of whole blood transfusions. Secondary operations were performed after normal levels were established and further replacement was continued as needed. German prisoners were observed to have a secondary anemia greater than that found in the American wounded, and this may have been an added factor related to the common observation that wound healing in the former group was notoriously poor.

SUMMARY AND RESULTS

Comparison of the types and results of treatment in groups of patients with war wounds requires qualification as to the point in evacuation where the observations were made. The highest mortality of cranial wounds occurs on the battle field itself. Little information exists as to the character of these early fatal wounds. The nearer the front line the higher the mortality (25). The casualties who survive wounds for at least 8 hours reach evacuation hospitals, field hospitals, or similar units for definitive surgical treatment. Death serves to process the wounded during the early hours of injury. The greater number of neurosurgeons available in the American army resulted in the performance of operations upon severe and extensive wounds. In other armies the "more hopeful" of the "bad" (178) lesions were operated upon after minor injuries with absent or minimal neurological signs and then the more severe penetrating wounds, in order of their severity were treated. Some observers (24, 130, 138) have pointed out that the purpose in the neurosurgical treatment of cranial wounds of war is not life saving but the prevention of infection in survivors of such wounds. The process of primary debridement, toward that end, which is usually performed in the Evacuation Hospital is none the less associated with a significant mortality. Secondary debridement at a General Hospital, again in survivors, is also attended by an occasional death. Any evaluation must, therefore, be made only in consideration of the corresponding time and place relationships, and the type of cases selected for operation. This is strikingly true in a review of penetrating wounds of the brain in civilian life. In this class, one-half of the patients who are brought to the hospital die within 6 hours of admission.

Information is now available concerning the care of cranial wounds of World War II at Ameri-

can evacuation hospitals and at British casualty clearing stations or mobile field units. Table IV summarizes reports which have appeared in the recent literature.

The following patients with war wounds considered in this review were observed by Webster Schneider and Lofstrom after reaching a general hospital having in most instances been previously operated upon at evacuation hospitals. Most had survived their injuries and operation for from 5 to 10 days. There were 198 patients with penetration of the dura and brain and 62 with compound fractures in which the dura escaped penetration. Forty German prisoners of war have not been included in the statistics except in the summary of orbitocranial and cerebellar wounds. There were 84 patients with wounds of the scalp requiring neurological observation. The mortality was 6.4 per cent among 260 patients (Italy 146 cases mortality 6.8%; France, 114 cases, mortality 6.1%). The wounds were caused by shell fragments in 75 per cent of the patients and by bullets in 14 per cent. In 11 per cent the cause was unknown. A summary made in several groups and based upon the type of management required in treatment rather than upon the type of pathological damage produced is given as follows.

Wounds of the scalp (84 cases—0 deaths). The patients in this group reached the general hospital usually because of a significant degree of persistent headache which warranted further rest and observation. Wound infection occurred in 15.4 per cent of these patients, which delayed early return to duty. Pneumoencephalograms were taken of 8 patients who presented symptoms and

signs suggesting subdural hemorrhages. None was found. It was not unusual for patients in this group to require neuropsychiatric attention; their complaints being due to psychoneuroses.

Wounds without dural penetration (62 cases—1 death). The dura was inspected at the time of the removal of the depressed bone fragments in all but 11 of this group of patients. Extradural hemorrhages were found in 3, and subdural hemorrhages in 2; 1 of these patients manifested the complication by Jacksonian convulsions. Four patients presented major neurological disability in 3 of these the dura was observed to be normal. One patient died, trephining being done at the time of failure. Autopsy showed that death was due to diffuse intracranial injury. An encephalographic study was made of 1 patient in this group. Trepanation at the site of a linear fracture was not routinely performed, although it was said to be of value by Haynes (89).

Wounds with dural penetration (198 cases—16 deaths).

The management of wounds with varying degrees of dural and underlying cerebral injury followed in general the principles outlined in the operative technique of primary débridement previously considered. Almost routinely a graft of

cia lata followed by a split thickness graft to the defect.

pericranium, temporal fascia or fascia lata was used to close the dural defect when necessary. For example the dura was closed in all but 2 cases of the 50 cases in this group the condition in these 2 cases not permitting further expenditure of time at operation. Among this group of 50 cases, a "preserved" dural graft was employed in 5 patients. The dura was obtained from cadavers and preserved in formalin and then alcohol (177). The observation of "damming back of infection" when closure of the dura was employed, as reported in World War I was not made.

Patients with gutter type wounds almost uniformly sustained massive anatomical damage to the scalp skull, and brain. This type of wound was less commonly observed, probably because of the fact that survivors were less frequent. The observation that the pathway for infection is maximum is supported by the fact that brain abscess developed in 9 patients of this group, an incidence of 43 per cent. The policy of tight closure of all wounds at primary débridement regardless of the degree of infection contrary to that of World War I in which the wound

was left open for free drainage, appears to be well founded. It is of interest that relaxing incisions were not employed in the care of gutter wounds with major loss of scalp. Closure was effected when mobilization of the scalp failed, by means of a flap swung into the craniotomy site, and a bare area of pericranium was left for grafting.

The depth of track damage was usually greater upon penetration by a metallic missile. The potential contamination was also greater because of the fact that fragments, especially those larger than 1 centimeter bore organic material upon their surfaces. This was true particularly of ragged missiles in contrast to smooth bullets. Shell fragments may be covered with tiny bone particles adhering to the surface. The threat of later complications would appear to be considerable when such fragments are retained. A policy of removing all accessible metallic, as well as bone, fragments was followed when such missiles had not been removed at primary operation.

Survivors of wounds involving the ventricles were infrequently encountered. Contrary to the observation in World War I opening of the

WEBSTER, GURDJIAN PENETRATING CRANIAL WOUNDS

(Legend on opposite page)

ventricle per se in the course of débridement did not significantly increase the mortality probably because of the protection afforded by chemotherapeutic substances. Control of infection was possible, even when the ventricle was entered in the course of debriding a complicating cerebral abscess.

Few patients with perforating wounds survived. The principles in management were similar to those for the less severe penetrating injuries. The wounds of exit, entrance and of the entire track were débrided. The dura was closed by means of grafts if necessary. Only 1 patient was found to survive a perforating injury involving both hemispheres which had been caused by a small shell fragment.

Venous sinus wounds requiring heroic efforts directed at hemostasis ligation muscle grafts and fibrin foam were sometimes encountered. Adequate exposure was of importance. Money (130) believes that the outlook for a return of cerebral function is 'bad' when the sagittal sinus has been completely torn across and requires ligation. We have noted complete neurological recovery in ligations up to the Rolandic

point as has been previously observed by Cush

Orbitocranial wounds (40 cases—5 deaths) The cases placed in this group were limited to those which involved the orbit and the frontal area of the skull and they were considered separately in view of the special type of management often necessitated. The management of this group of wounds has been reviewed in detail (211). The injuries of this type numbered 40 and were divided into two groups—Group I numbering 20 patients who presented severe destructive anatomic injuries to one or both globes in addition to the skull and brain injury. Group II also numbering 20 patients, but these presented wounds which involved the orbit and brain with varying degrees of physiological injury to the contents of the orbit. Massive wounds involving the orbit and frontal area with associated injury to the paranasal sinuses could not be treated by conventional methods of débridement and closure because of the loss of tissue. A suitable method for treating this type of injury was the employment of a temporary graft of fascia lata to close the dural defect. The graft was removed after 15

Fig. 6 Fan blade injury of the right frontal lobe. A 25 gm. intracerebral clot as removed from the missile track. The injury was caused by a broken off blade of an automobile fan connected to a 10 volt circuit and consequently

running at a much higher speed. There was no immediate post-traumatic unconsciousness. About 4 hours after the accident the patient became comatose undoubtedly because of the enlarging blood clot in the missile track (31).

days and a split thickness graft was then applied to the granulating area of involvement (Fig 5). Particular attention was given to the total débridement of the sinuses by removal of all de-vitalized tissue, bone fragments, clots and sinus mucous membrane. Schorstein (171) recommended radical débridement in wounds of the fronto-orbital region and the employment of a soft paraffin gauze pack in the open wound. A plaster-of-paris skull cap was then used as a routine dressing.

Other factors probably include the protected anatomical location of the cerebellum and the adequate covering afforded by the steel helmet which was available in World War II. This type of injury which presents the possibilities of rapid and serious complications, demands exploration as early as possible and is thus a problem for the evacuation hospital neurosurgeon. There was 1 death in this group of patients 8 presented minimal neurological defects.

MILITARY CIVILIAN CORRELATIONS AND CONCLUSIONS

In civilian practice bullet wounds constitute almost all of the high velocity injuries in military experience only 15 per cent of cranio-cerebral injuries were caused by bullets, as seen in a general hospital, and while wounding by shell fragments is unknown in civilian practice 75 per cent of the cranial cerebral wounds in war belonged in this class (310). The majority of bullet wounds in military practice are fatal because of the velocity and size of the missiles. Most bullets for war use are encased in a metallic casing and have a pointed nose. A great many of the civilian bullets are round nosed. Frequent fragmentation and dispersion of fragments through the area of impact are common with the latter. In view of the lower velocities in civilian bullet wounding, is not as marked and therefore there is less pulsing at a distance from the track.

Among the low velocity penetrating wounds of the head are perforation by knife blade, car door handle, golf stick, umbrella end, brick, and various other everyday objects. The management of

An osteoplastic flap used for exposure of the frontal fossa was found to be of value in wounds with penetration produced by small metallic fragments which entered the orbital roof and the frontal lobe at the base of the skull. This exposure allowed débridement at the site of the bony injury and of the brain as well as the repair of the dura either by suture or graft. Distortion of the frontal area through loss of bone was thus avoided. In 5 of the 40 cases in this group brain abscess developed an incidence of 12.5 per cent.

Wounds involving the cerebellum (10 cases—1 death)

It was observed that wounds of the cerebellum were infrequent. Ten cases (an incidence of 3%) were encountered (319). World War I reports indicate so even lower percentage of 54 (6 cases in 1108)—(127). In 9 of the 10 patients the wounds were located on the left side of the cerebellum, and they were caused by shell fragments in all except 3 cases. In 3 instances the wound of entrance was located in the neck and the associated cerebellar injury escaped attention. The infrequency of cerebellar wounds is probably due to a low incidence of survival among patients with wounds involving the posterior portion of the

WEBSTER, GURDJIAN PENETRATING CRANIAL WOUNDS

Fig. 7. Bullet wound of head seen two years after trauma for headaches. Examination showed choked discs and evidences of motor irritation in left lower limb. Suspected cyst about bullet was disproved by air cephalograms. The first operation consisted of decompression and tapping for a possible cyst. Decompression was thought sufficient

but this only cured the complaints. The area of decompression grew to massive size. A second operation was done for removal of the pressure signs. Apparently the bullet behaved like a brain tumor and cure could not be effected without its removal (82)

such wounds deserves only a passing comment. Aside from the possibility of injury to the blood vessels with consequent formation of mass lesions (81) low velocity penetrating wounds of the brain do well under conservative management by careful débridement of the wound of entrance and inspection of the skull and dura. If the fragment is still in the cranial cavity it is removed. Obviously pulped and necrotic tissue is sucked away. No extensive track débridement is necessary but with lacerations of the brain the possibility of intracerebral hemorrhage should be kept in mind. The removal of large clots from the area of the wound may be lifesaving. In Figure 6 are seen the x ray films of the skull of an adolescent youth. A broken-off fan blade is seen in the right frontoparietal region near the midline. Although conscious on admission within 2 hours he became semiconscious and before operation he was comatose. Following the removal of the fan blade a 22 gm. intracerebral clot was evacuated from the missile track. The patient awakened within a few minutes while on the operating table. Usually low velocity penetrating wounds, if seen in the acute stage, do well, but careful observation for complicating meningitis and/or brain abscess is recommended. In the cases in which a penetrating wound of the head with the foreign body still in the brain the fragments should be removed since the possibility of eventual infection about the foreign body is ever present. Dretzka (56) reports an instance of brain abscess about a broken knife blade in the left occipital lobe the

injury having been sustained 10 years previously. The abscess and the broken knife blade were removed and the patient recovered. There is no valid reason that easily accessible foreign bodies should not be removed even if they are asymptomatic.

Penetrating craniocerebral wounds of civilians by bullet and low velocity missiles have been the basis for only a few articles since World War I. The reviews by Hanson (86-87), Pilcher (152), Walker (207) and the articles by Coleman (38), Goode (73), Gurdjian and Buchstein (82) and German Brody and Harvey (69) complete the American list. Goode (73) discusses the cases seen in the Cincinnati General Hospital. Of 105 gunshot wounds of the head, 96 presented dural penetration and a mortality of 80.3 per cent resulted. All of 34 patients with perforating wounds died. In 2 patients retained bullets caused no symptoms for a 10 year period in one and an eight month period in the other. Thirty-one patients were operated upon with a mortality of 45.1 per cent. Goode suggests excision of the wound, of fragments of bone and of the foreign bodies if possible. A fascia lata transplant is recommended for dural repair. Gurdjian and Buchstein (82) reviewed cases of gunshot wounds of the head treated at the Detroit Receiving and Grace Hospitals. Of 45 patients 11 had no fracture of the skull while 34 had fracture of the skull and penetration of the dura or both. Among the group with no fracture 1 had a left parietotemporal subdural hematoma. Of the 34 with fracture of the skull and penetration of the dura or both 16

INTERNATIONAL ABSTRACT OF SURGERY

Fig. 6. This patient presented a cerebrospinal rhinorrhea associated with meningitis, cortical ulceration, and an intractable wound. Management consisted of secondary débridement with closure of the dura by means of a temporary graft of fascia lata, which was removed later. The open wound was subsequently covered with a split thick skin graft.

died in 9 hours or less and 5 died in 26 hours or less. It was concluded that the state of consciousness is of prognostic significance in this class of patient. These authors group their cases into three classes: first, unconscious and moribund; second, semiconscious and responsive to stimuli; and, third, conscious. In the first group all died within a few hours after entrance into the hospital. The patients in the second group carried on long enough to develop evidences of increased intracranial pressure, hyperthermia, and hyperpnea. An initially low pulse rate was usually followed by a rapid, thready pulse. Five of this group died in 26 hours or less after entrance into the hospital. Among 11 patients who were conscious on entrance 9 recovered and 2 died 1 having received operation. These authors similarly suggest early operation for débridement—removal of bone fragments pulped brain tissue and metallic fragments if possible. German, Brody and Harvey (69) review a group of compound cranio-cerebral injuries. Of 64 patients, 9 had bullet wounds of the head, 6 died, 1 before operation. All traversing wounds terminated fatally.

In the preparation of the present review 100 cases of dural penetration by bullets were reviewed from the records of the Receiving and Grace Hospitals for a period of 20 years. Eighty-three patients died 63 died in less than 12 hours, 9 additional died in 48 hours or less, and the remaining 11 carried on from 3 to 42 days. The prognostic importance of the state of consciousness was again evident. It seems fair to state that among the 11 who survived from 3 to 42 days, timely and total débridement might have saved some lives.

In comparing military and civilian experiences the mortality from bullet wounds of the head in civilian life seems appalling. One reason for this high mortality is that most civilians who survive the immediate injury reach a hospital before death while in military practice comparable cases are seldom seen at an evacuation hospital because of the lack of equally rapid transportation.

It appears that the proper management of penetrating wounds of the brain by high velocity missiles was well worked out at the conclusion of the last war on theoretical grounds. During World War II, with the help of better trained personnel, and the necessary instruments for proper operative intervention a practical demonstration of what could be accomplished was given. A thorough débridement, removal of all foreign organic matter and removal of all brain tissue was accomplished in many instances with no sequelae of infection weeks or months later. The use of chemotherapeutic or biologic agents to fight infection has undoubtedly been of inestimable value but they alone and without careful débridement would have failed. In the following few paragraphs the management of civilian craniocerebral bullet wounds is considered, as well as the lessons learned from war practice which may be applicable to civilian practice.

Unless a patient with a bullet wound of the brain is in a moribund state on entrance, all effort should be made to give supportive and resuscitative treatment. It is probably true that little can be accomplished for those who will die within a few hours of the injury. For some of those who resuscitate, operative management to remove blood clots from the bullet track with careful débridement may be lifesaving. The importance of careful and complete débridement cannot be overemphasized for upon it depends the prevention of late sequelae in the form of meningitis and/or brain abscess. Long curved incisions may be used to expose the skull defect, and the bone may be resawed away rather than removed.

masse to expose the dural defect. Careful débridement of the dura, brain and the track are then carried out with the aid of suction. The electrocautery is used for hemostasis. The use of fibrin foam or cellulose cotton with thrombin may be indicated in some cases. The dural defect is repaired with fascia lata or temporal fascia. The value of whole blood transfusions during the operation cannot be overemphasized.

Metallic foreign bodies in the cranial cavity should be removed whenever possible. There is no reason for leaving them in the cranial cavity if they are easily accessible. Foreign bodies which have lodged in the cranial cavity for many months or years, such as broken knife blades or ice picks, should be removed. An inaccessible bullet which may remain asymptomatic for many months or years may eventually cause symptoms necessitating operative removal (Fig 7).

There is a difference between civilian and military forms of brain abscess. Simple drainage of a brain abscess following a gunshot wound is seldom successful. Excision of the abscess, fragments of bone, hair and other foreign material is mandatory if a good result is expected. Civilian abscesses can be drained with success (40, 72, 167, 172). There is some evidence to show that late sequelae following civilian abscesses cured by drainage are fewer and less serious than those occurring after the abscess has been excised or allowed to extrude (42, 74). However radical attack of civilian brain abscesses is advocated by King (112, 113), Kahn (111), Vincent (201, 202), Pennybacker (148) and others. Vincent taps the abscess and later excises it like a deep seated abscess and later excises it like a deep seated abscess. In civilian practice the location of the abscess may be important for deciding on the type of management (drainage or excision). Excision may be more seriously considered in the silent portions of the brain but if an abscess were located immediately beneath the motor centers drainage with cure may result in less disability.

In an earlier article on the present authors rhinorrhea due to trauma the present authors (83) discussed the seriousness of cases with communicating brain abscess and meningitis. Excision of the abscess in such a case and exposure of the plicating and repair (fascial transplant if necessary) fistula and repair (fascial transplant if necessary) can be entertained seriously in a manner described for military crani-orbital wounds by Webster, Schneider, and Lofstrom (210) (Fig 8).

With the aid of chemotherapeutic and biologic agents, early careful and complete débridement becomes a well established procedure in craniocerebral bullet wounds both to minimize post-traumatic infection and occasionally to save life.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Lubchitz, K. Adamantinomas of the Jaw with Reference Especially to Their Treatment *Acta Radiol., Stockh.* 1945 26 447

Adamantinomas are epithelial tumors which occur chiefly in bones and especially in the jaws the lower jaw being affected more frequently than the upper. Though the tumor is benign histologically it often proves clinically malignant, because of its particular features. It may recur despite repeated surgical intervention and may be responsible for a fatal outcome.

In the jaw at least adamantinomas occur a little more frequently in women than in men. Most often the tumor develops between the ages of 20 and 40 years but it has been found as early as at birth and as late as at the 76th year of age. Its growth is slow and in the beginning it does not give rise to symptoms but as it increases in size it causes the bone in which it is situated to expand. This first interferes with chewing later, deglutition and respiration may become difficult there may be pain and hemorrhages, perhaps spontaneous fracture. Owing to the slow growth however it may often be several years before the symptoms become so marked that the patient finds it necessary to consult a physician.

Morphologically, two forms of adamantinoma may be distinguished solid and polycystic. The former is the rarest. The etiological connection between the adamantinoma and the enamel organ is shown by the similarity of the microscopic structure. Operative removal of the tumor has been practiced ever since its nature was recognized. Both enucleation cauterization, and resection of the portion of bone containing it are mentioned in the literature.

The author gives an account of 11 cases of the disease. The patients were treated at the Radium Center in Copenhagen, during the period from 1932 to 1943. Seven of the patients were males and 4 were females. In 7 patients the tumor was situated in the upper jaw and in 4 the lower jaw. Eight of the tumors were cystic, 3 were solid the latter occurred in the 3 youngest of the patients.

The roentgen examination is an important aid in the diagnosis, which especially in tumors of the lower jaw may often be established with considerable certainty on the basis of the roentgenologic picture. In the film the tumor appears as a well defined rarefaction or as several more or less confluent rarefactions, which often cause expansion of the bone. In the upper jaw the picture is less characteristic, the tumor often (at least in the beginning) shows itself only by a blurring of the maxillary sinus

sometimes by an expansion of the latter and only after some time do also signs of destruction of the bone appear. Only the histological examination, after biopsy or operation, makes the diagnosis absolutely certain.

The author discusses the therapeutic results and stresses the clinical malignancy of the tumors, as contrasted with their histological benignity. She points out that the clinically malignant character of adamantinomas makes complete primary removal important—in the case of solid adamantinomas by enucleation, and in the case of cystic adamantinomas by resection. Roentgen treatment can only be used as a palliative measure.

JOSEPH K. NARAT, M.D.

EYE

Kekchever K. K.: Methods of Accelerating Dark Adaptation and Improving Night Vision *Wor Med., Chic.* 1945 8 209.

The author discusses methods of accelerating the dark adaptation of the eye with the view of improving night vision. Methods include (1) regulating the adaptation before passing into darkness (2) wearing goggles with colored lenses (3) exposing the eyes to white light (4) exposing the eyes to red light and (5) employing gustatory and olfactory stimuli. These methods are not equally valuable. The choice of method used depends on the circumstances at the time of adaptation.

HOWARD H. ROMADKE, M.D.

Hardy L. H., Rand G., and Rittler M. C.: Tests for the Detection and Analysis of Color Blindness: An Evaluation of the Ishihara Test *Arch. Ophth., Chic.* 1945 34 295.

In this article the author and his coworkers evaluate the Ishihara test. They believe that the test is a gross one for defective red and green vision but fails to classify the type of color vision. For this reason it cannot be used to give a satisfactory evaluation no matter how carefully it is administered.

HOWARD H. ROMADKE, M.D.

Shapland, C. D.: Two Cases Showing Unusual Intracocular Foreign Bodies. *Proc. R. Soc. Med. Lond.* 1945 38 663.

In this article the author describes 2 unusual cases of intracocular foreign bodies one of which showed the possibility of the retention of nonmagnetic metallic fragments in the eye for five years with no evidence of inflammatory complications and no evidence of degeneration from chemical action. In the second case the eye retained multiple particles of

INTERNATIONAL ABSTRACT OF SURGERY

stone without evidence of pyogenic infection. The absence of this infection apparently is due to sterilization of the particles by the heat resulting from the explosion at the time of the accident.

HOMER H. ROWLAND, M.D.

Struble, G. C. and Kreft, A. J.: War Injuries of the Eyes and Visual Pathways. *War Med.*, Chic., 1945 8: 292.

The authors discuss the factors leading to eye injuries in warfare and the type of injuries sustained and illustrate the various forms encountered. They note that serious lesions of the eyes, including macular disturbances, may be caused by blast concussion alone, without any penetrating injury. Penetration of the orbit by minute shrapnel fragments which do not penetrate the globe may also cause serious intraocular damage. No cases of ocular injury following severe war trauma of the mandible were encountered and the authors believe it possible that the temporomandibular joint may absorb some of the concussion. Severe unilateral facial wounds have resulted in damage to the eye of the same side, but never the opposite eye.

All persons who have been exposed to a severe blast or who have incurred war wounds about the head should have a thorough eye examination, especially as to fundi and visual fields. There should also be a complete roentgenological examination of the skull, the facial bones, both orbits and the optic foramina for evidence of fracture or foreign body.

WILLIAM A. MARK, M.D.

DeVoe, A. G.: Surgery of the Anophthalmic Orbit. *Am. J. Ophth.*, 1945, 28: 1346.

An opportunity to see a large number of anophthalmic sockets in military service has resulted in an analysis of some of the difficulties encountered in the use of a properly fitting prosthesis. The commonest use of a properly fitting prosthesis seems to be the retraction or single cosmetic blemish seems to be the retraction or sinking of the upper lid with loss of the normal lid crease. This may be due to a change in the normal direction of pull of the levator, to loss of orbital tissue, to atrophy of the orbital fat, to overlapping of the muscles over an implant with the levator pulled down by the superior rectus, or to use of a large implant, as has been suggested by various authors. It is difficult to overcome this by changing the shape or size of the artificial eye. Attempts to overcome this difficulty have been attempted by (a) severing the attachments of the superior rectus and the levator at the time of enucleation, (b) delayed implantation of a glass sphere, (c) implantation of cartilage on the floor of the orbit, and (d) dermal graft to the upper lid.

The results of the first method are inconclusive. As to the second method, it is often difficult to find a Tenon's capsule for delayed implantation, especially under general anesthesia, and in general this method was found unsatisfactory. If there is a depression of the floor of the orbit, cartilage may be implanted subperiosteally. The author has had

good success with dermal grafts in these cases. Thick skin from the back is implanted high and superficially beneath the skin of the upper lid, using two layers.

The next most common defect is one which usually occurs after an artificial eye has been worn for many years: there is difficulty in retention of the eye due to a relaxation of the orbicularis. An operation similar to Wheeler's method for shortening the orbicularis in spastic entropion may be performed, and the author used this method in 4 cases, with success in 2. In the 2 cases in which this operation was not successful, the defect was corrected by the use of a mucous membrane graft after dissection of the conjunctival surface below the tarsus.

The author believes that the use of skin grafts in the socket should be avoided because of the resulting discharge and odor, especially where both skin and mucous membrane are present.

The surgical procedures described should be used only after all attempts to correct the defect with a properly fitting eye have failed.

WILLIAM A. MARK, M.D.

Reese, A. B.: The Iridodectomy Operation for Glaucoma. *Arch. Ophth.*, Chic., 1945, 34: 356.

Of 61 eyes upon which the author performed an iridodectomy operation for glaucoma, the disease was arrested in 33 and in 9 the results were considered unsatisfactory. Failure in 2 cases was believed to be due to a poorly placed incision. In the remaining 7 the patients had undergone previous trephine operations or had shown uveal pathology and were therefore unsuitable for this method of surgery.

The author emphasizes the importance of making the keratome incision in the sclera 3 mm. behind the limbus, and producing an iridodialysis, leaving both iris pillars incarcerated, which suggests some variation in technique from that which is usually employed. He prefers to incise the conjunctiva with the keratome 10 mm. from the limbus, dragging it down to the point of incision in the sclera rather than to make a clean dissection down to the sclera before inserting the instrument.

It is emphasized as has been brought out by others, that this operation is most useful in cases in which the intraocular tension is not too high—preferably under 50 mm. Hg. (Schlötter). It is not indicated in cases of long standing, in aphasia, or in cases in which previous operations for glaucoma have been unsuccessful.

The author has encountered no serious complications with the operation, and has thus far observed no instance of sympathetic ophthalmia following it.

WILLIAM A. MARK, M.D.

Muldoon, W. E.: Restoration of Patency of the Nasolacrimal Duct. *Am. J. Ophth.*, 1945, 28: 1349.

The author has placed vitallium tubes into the nasolacrimal duct in 4 cases of stenosis of the duct with a fairly good end-result in at least 3 of the cases. The principal advantage of vitallium is its

SURGERY OF THE HEAD AND NECK

lack of tissue reaction the metal may be left in position permanently, and for this reason it has had widespread use, especially in orthopedic surgery. Doherty first reported its use in ophthalmology as an orbital implant.

The author exposed the lacrimal sac by a 13 mm curved skin incision and through a small incision in the sac curetted the nasolacrimal duct and then placed the vitallium tube into the bony canal. The in the shoulder resting on the rim of the canal. The cushion in the sac was closed with 000 plain catgut and the skin and subcutaneous tissues were sutured in the usual manner. A pressure bandage was applied for several days, and the canal irrigated through the upper or lower punctum one or two weeks later.

It was found that in most cases a tube 3 mm in diameter could be inserted without difficulty. Because the metal is extremely hard it must be cast and therefore the walls cannot be less than 0.5 mm in diameter. This inside diameter of 2 mm seems to be adequate for drainage. The length of the tube is 13 mm., which the author believes to be desirable. In one case, a tube 2 mm in diameter was used leaving a lumen of only 1 mm which does not seem to be adequate.

The author points out the advantages of this procedure over a dacryocystorhinostomy and the improvement reported in his cases would seem to justify further use of this method. X-ray films of the tube in position are reproduced.

WILLIAM A. MANN, M.D.

Reis, J. L.: A Corneal Graft Operation for Recurrent Pterygium. *Bril. J. Ophth.* 1945 29 637

The author describes a corneal graft which he uses in association with pterygium operations in order to prevent the postoperative cicatricial opacity with subsequent vascularization which occurs following the general surgical procedure. He believes that the optical and cosmetic results are better and that there is less likelihood of recurrence. The technique is plainly described.

HUNTER H. ROMAN, M.D.

Krause, A. C.: Congenital Cataracts following Rubella in Pregnancy. *Ann. Surg.* 1945, 122 1049.

The author reports 5 cases of congenital cataract which followed rubella in pregnancy, and discusses the preventive, conservative and radical treatment of fetal rubella.

In Australia an unusual number of congenital nuclear bilateral cataracts appeared as a mild epidemic in infants. Damage to the lens evidently occurred during the first few months of pregnancy in mothers who acquired German measles during the second or third month of pregnancy. The cataracts were associated with many other congenital defects. Mental retardation occurred in 4 infants, congenital deaf mutism in 11 and heart lesions in 11.

In a series of 124 cases reported in the literature in which pregnant women were diagnosed as having rubella, 96 infants had cataracts.

In view of the seriousness of the complications therapeutic abortion should be considered if the disease has occurred in the first 4 months of pregnancy. Treatment with convalescent serum should also be considered. Krause stresses the importance of early surgical treatment of the cataract before the ability to develop fixation is lost. This would be before the age of 3 months.

JOSEPH ZUCKERMAN, M.D.

Scholz, R. O.: Epivascular Choroidal Pigment Streaks, Their Pathology and Possible Prognostic Significance. *Bull. Johns Hopkins Hosp.*, 1945 77 345

The author describes 5 cases of epivascular choroidal pigment streaks, rosary streaks of Siegrist, and reviews the literature on this subject.

The majority of the patients considered had hypertensive cardiovascular disease and in some of them renal involvement was indicated. It was possible to follow up the study in 1 instance with autopsy findings. Anatomical reconstruction indicates that the ophthalmoscopic picture is produced by proliferation of the epithelium over partially sclerosed choroidal arteries. It is suggested that the presence of these streaks is of prognostic value, and in the majority of cases a poor prognosis is indicated.

HUNTER H. ROMAN, M.D.

Rodin, F. H.: Hypertensive Retinopathy Associated with Adrenal Medullary Tumor (Pheochromocytoma): A New Clinical Entity. *Arch. Ophth.*, 1945 34 403

Pheochromocytoma is a rare form of chromaffin tumor arising from the embryonic sympathetic nervous system. The adrenal medulla is composed of chromaffin cell tissue hyperplasia of which is considered the rarest form of adrenal tumor. It is characterized by a train of hypertensive changes, including definite ocular changes. Epinephrine or an epinephrinelike pressor substance is contained in the cells of the tumor. This substance freed in the bloodstream causes vasoconstriction, elevation of the blood pressure and stimulation of the sympathetic nervous system. In the eye there is a typical hypertensive retinopathy.

In a case reported by the author there was an extensive retinopathy of a hypertensive type with hemorrhage and exudates. These findings disappeared following removal of the tumor. Serial fundus photographs illustrate the findings in the eyes prior to and after removal of the pheochromocytoma. The author believes that this is a new clinical entity which should be called a hypertensive retinopathy associated with adrenal tumor.

WILLIAM A. MANN, M.D.

Bedell, A. J.: Clinical Differentiation of Emboli in the Retinal Arteries from Endarteritis. *Arch. Ophth.* 1945 34 311

The author describes a means of differentiating emboli in the retinal arterial system from endarteritis.

teritis. In cases of embolism the arteries become mere threads and are greatly reduced in size, whereas in endarteritis the arteries are not as small as those found in embolism. In addition, in the latter case there are always white plaques along the walls of the vessel. In embolism the retinal edema is limited to an oval area which includes the disc and macula while in endarteritis the edema usually involves the entire visible fundus. In cases of endarteritis there is always some evidence of pre-existing arterial disease—increased reflex from the vessels irregularity of vessel caliber indentation of the veins, and exudates, hemorrhages, or other signs of arteriosclerosis and hypertension.

HUTCHER H. ROMADRE, M.D.

EAR

Henry G. A.: Blast Injuries of the Ear. *Laryngeology*, 1945 55 663

In this article are presented the findings and impressions gathered from 592 men sustaining blast ear injuries. These cases were seen during the Battle of Europe at a large hospital part time under canvas and later in buildings. They came chiefly from infantry and armored units.

Tinnitus was the most common and by far the most persistent of the symptoms. It occurred in one ear in 124 patients and in both ears in 48. Usually it lasted for from only a few days to a month, but in a large minority it persisted continuously for from a few months to a year. Vertigo was not a prominent symptom. A few of the men stated that they found blood in their ears shortly after the blast many more found a slight discharge a day or two later. On examination however it was surprising to find how few had evidence of blood in the canal or middle ear. Headache of the usual frontal parietal, or occipital variety was occasionally a complaint, but it did not occur more frequently in this group than in a similar number of soldiers without blast ear injuries. One hundred and fifty two patients suffered perforation of the ear drum, 124 had a single perforation of 1 eardrum, 12 a double perforation of 1 drum and 16 had a single perforation in both tympanic membranes. Hemorrhagic areas of the drum were present in 36 cases. External otitis was present in 1 ear canal in 30 times, and in both ears 22 times.

In the beginning nearly all cases had a combination of conductive and perceptive deafness. The greatest hearing improvement occurred in the first 10 days most of this in the first 4 days. The majority of cases continued to show improvement in perception of hearing a few showed gradual deterioration. It seemed likely to the author that about two-thirds of the men would recover completely. Others would unquestionably be inconvenienced by loss of hearing in one ear and a smaller group would require the help of a hearing aid. Unfortunately a few will have so much loss of hearing that they will require instruction in lip reading.

NOAH D. FABRICANT, M.D.

Struble, G. C.: Penicillin Therapy in the Practice of Otolaryngology. *Arch. Otol.* Chic., 1945 47 317

The parenteral methods used for the administration of penicillin consisted of intravenous drip for the first 24 or 48 hours in the most severe infections, followed by intramuscular injections every 3 hours.

Local methods of application consisted of the instillation of isotonic sodium chloride solution containing 2 500 units of penicillin per 1 c.c. into the sinuses and mastoid cavities the filling of the paranasal sinuses with 1/4 per cent of ephedrin sulfate in isotonic sodium chloride solution containing 500 units of penicillin per cubic centimeter, and the dusting of postoperative mastoid wounds with 100,000 units of penicillin powder.

The following opinions were expressed, supported by illustrative cases. Parenteral penicillin therapy has a favorable effect in acute sinusitis but is not effective after acute and chronic empyema is present. Local therapy shows great promise in the empyema of sinuses. Penicillin therapy is effective in early stages of otitis media, but must be given in adequate doses over a long period.

Suppuration in the mastoid (masked) and came may be incompletely controlled (masked) and cause complications after withdrawal of the drug unless surgical drainage is instituted. Sulfonamide and penicillin therapy should be combined when intracranial extension is suspected.

In chronic otitis media without cholesteatoma or granulations and with a large perforation, penicillin given locally was sometimes useful in controlling local infection.

In cases of superficial cellulitis in deep infections involving the retropharyngeal, submaxillary and parapharyngeal spaces and in Ludwig's angina, penicillin was found to be more effective than sulfonamides in controlling the spread, but almost invariably surgical drainage was also required. Penicillin like sulfonamide compounds, can give an effect masking the presence of disease unless the physician is alert to this possibility. The general principles and indications for surgical drainage remain unchanged.

JOHN R. LUDWIG, M.D.

Lindsay J. R.: Osteomyelitis of the Petrous Pyramid of the Temporal Bone. *Ann. Surg.* 1945 121 600.

Lindsay states that the middle ear air spaces separate the marrow spaces of the bones of the vault from the petrous pyramid and other bones of the base of the skull.

Infection passes readily from marrow spaces to air cells, but extension in the reverse direction meets greater resistance. The cell system, therefore, tends to limit the spread of osteomyelitis between the vault and the base of the skull.

Osteomyelitis of the petrous pyramid sometimes occurs by the hematogenous route or by extension from other bones of the skull base, but it is usually a direct extension from middle ear suppuration.

SURGERY OF THE HEAD AND NECK

The dense labyrinthine capsule forms a barrier between the marrow-containing apex and the middle ear cell system in the majority of bones. In about 80 per cent of bones, however, the air cell system invades the apex and creates a direct entrance for infection and the possibility of osteomyelitis.

A tendency to obstruction of drainage created by a natural bottleneck, predisposes to the breakdown of cell partitions and invasion of surrounding marrow spaces in the apex.

Osteomyelitis tends to remain localized within the apex during the acute stages and responds well to surgical drainage.

Chemotherapy provides a valuable aid in localization but cannot be depended upon to cure without surgical drainage.

In the presence of sequestration or extension of the osteomyelitis to other bones of the base of the skull, the combination of chemotherapy and surgical drainage offers a means of avoiding dangerous complications, but may fail to eradicate the disease.

NOSE AND SINUSES

Lumaden R. B.: War Wounds and Injuries Involving the Paranasal Sinuses. *Edinburgh M. J.*, 1945 55 402

Twenty cases of wounds or injuries involving the paranasal air sinuses are recorded.

In 9 of these the frontal or frontoethmoidal region was involved while involvement of the maxillary or maxilloethmoidal region occurred in 11 cases.

The late operative procedures are described and technical points are discussed.

JOHN F. DELPER, M.D.

MOUTH

Parker D. B.: Observations on the Definitive Treatment of Maxillofacial Injuries. *J. Oral Surg.* 1945 3 320.

In examining and reviewing a large number of maxillofacial gunshot injuries or injuries from contact with high explosive missiles in the military hospitals designated as plastic maxillofacial centers one recognizes certain definite facts. The first observation is in great contrast to the observation of World War I in that the incidence of infection of the soft tissues and bone is much lower. Two or three months after injury we find comparatively few cases of osteomyelitis or necrosis involving the bones of the face and jaws. This is unquestionably the result of early intelligent treatment in the forward areas. The training of medical and dental officers in maxillofacial surgery and the assignment of these officers to teams working with the auxiliary surgical groups have certainly borne fruit in the better control of the wounds when these patients have been evacuated to the United States for intermediate or definitive treatment. The second observation is that there has been a much more intelligent effort to

stabilize the bones of the face and jaws in a more nearly normal, anatomic relationship. This has aided in avoiding the deformities resulting from the collapse of the bony supporting structures of the face often difficult to overcome in the definitive treatment. Wiring techniques have been accepted as an aid in primary treatment in the overseas theaters.

The medical officer has learned that the dentist is essential to the ultimate treatment of the maxillofacial injury just as the dentist realizes that the plastic surgeon is essential to completion of many of the oral operations and the cases as a whole. Mutual understanding as to the part that each should play and a knowledge of the ultimate requirements in function and appearance, have made the plastic maxillofacial services function to the ultimate advantage of the patient.

When there is a loss of bone in the mandible an adequate soft tissue bed in which a bone graft will eventually be placed is essential. An attempt to insert a bone graft in tense adherent cicatricial tissue will often result in failure. Such tissue should be replaced by tissue having a good circulatory bed and loose enough to accommodate a graft without pressure sufficient to alter its contour. Bony support is sufficient to withstand masticatory pressure or to aid in the retention of a prosthetic appliance is desirable before much of the flat surface plastic repair of the face is complete. Bone grafts in areas communicating with the mouth or in which residual infection persists (in the bed or adjoining lost bone) are of course doomed to failure although, with penicillin therapy, some of the implanted bone cells may eventually survive.

One of the most difficult problems attending the definitive treatment of maxillofacial injuries caused by penetrating missiles is the trismus resulting from the wounds adjacent to the coronoid zygomatic temporal area. The marked destruction of the temporal and masseter muscles as well as of the buccal and masseter muscles as well as of the buccal, coronal and masseter muscles in a dense fibrosis in this area, which either limits or obliterates altogether the masticatory function of the mandible. Attention should be given both to preventing the maximum amount of fibrosis and to correcting functional disability.

Another problem in the definitive treatment of maxillofacial injuries is that of adhesion of the buccal mucous membrane to the alveolar ridge of the maxilla or of the maxilla, which obliterates partially or entirely the vestibule of the mouth. Such deformity limits the motion of the lips or of the buccal muscles which results in limited motion of the facial muscles of expression. It also limits the ability of a patient to wear a prosthetic appliance to assist in functional mastication, or for cosmetic use, to improve the contour of the face. Such conditions can be treated only by deep incisions through the adherent cicatrix and the interposition of a split graft over a stent mold held rigidly in position.

LOUIS T. BYARS, M.D.

Cook, T. J. Royster H. P. and Kirby G. K.: The Treatment of Gunshot Fractures of the Mandible. *J. Oral Surg.* 1945, 3 356

Certain essential steps should be followed in the treatment of gunshot fractures of the mandible. Control of hemorrhage, establishment of an adequate airway, temporary immobilization of the fractured bone, and treatment of shock are to be considered first. This is followed by minimal primary excision, without suture except when conditions are favorable for primary closure, and early immobilization of the fractured bone. Secondary minimal excision and debridement are done from 5 to 10 days after the injury accompanied or followed by delayed primary closure of the skin wound. The authors recommend treatment of osteomyelitis by early radical operation. LOUIS T. BYARS, M.D.

McNeely R. G. D.: Adenolymphoma of the Salivary Glands. *Canad. M. Ass. J.* 1946, 54 124.

Five cases of adenolymphoma of the parotid gland are reported. This type of tumor is infrequent, only 3 cases having been found among 155 salivary gland tumors seen in the Toronto General Hospital pathological laboratory in a 10 year period. Only 2 cases of malignancy have been reported in the literature. The tumor becomes apparent as a slow growing mass near the angle of the lower jaw usually in the fifth, sixth, and seventh decade. Subjective symptoms are absent and the growth is encapsulated and easily removed. It is composed of tall, doubly placed acidophilic cells which line the ducts and glandlike arrangements into which may project papillae and which may be dilated to form cystic spaces. The epithelial structures are supported by a lymphoid stroma with active germinal centers.

The genesis of the tumor is discussed and reasons advanced in favor of the hypothesis that it arises from salivary duct epithelium. The lymphoid tissue apparently serves as a supporting stroma and appears to participate in the neoplastic process.

NECK

McArthur J. W., Rawson, R. W., and Manna, J. H.: Idiosyncratic Febrile Reactions to Thiouracil: Clinical Characteristics and Possible Pharmacologic Significance. *Ann. Int. M.* 1945 3 915

Thiouracil was employed in the preoperative preparation of 104 patients suffering from thyrotoxicosis. Toxic reactions (applying the term in the most inclusive sense) occurred in 15 instances. In 5 cases fever was the most conspicuous feature of the reaction. The case reports of 3 patients who developed fever are presented, with speculations as to the fundamental significance of the idiosyncratic response.

The sudden onset of fever after a relatively constant latent period of 10 days, the explosive immediate reaction upon readministration of the drug and the character of the accompanying symptoms suggest that thiouracil reactions are manifestations

of the true drug idiosyncrasy. A review of the literature on the nature of thiouracil reactions revealed the fact that attention has been focused on factors which may predispose an individual to develop an idiosyncratic reaction, while the precise chemical factors which render an agent capable of inducing hypersensitiveness have been largely neglected. It is pointed out that the sensitizing capacity of a drug depends upon chemical structure and that hypersensitivity may be developed to the molecule as a whole or to certain radicals of the molecule. Propensity to induce idiosyncratic reactions is strong presumptive evidence of a drug's capacity to become bound to protein. It is suggested that capacity to bind proteins is the common chemical factor which is responsible for the anaphylactoid complications of chemotherapy as well as the therapeutic effect. The prevention of thyroid hormone formation by the sulfonamides and thiouracil may prove to be due to an enzyme blockade mechanism.

JOHN L. LINQVIST, M.D.

Kesting, F. R., and Cook, E. N.: Recognition of Primary Hyperparathyroidism. *J. Am. M. Ass.* 1945 139 904.

Clinical hyperparathyroidism may be divided into three groups, in accordance with the extent of the skeletal involvement. Group 1 comprises the cases with the classic picture of osteitis fibrosa cystica generalisata. Group 2 consists of cases with atypical demineralization of the skeleton, and group 3 includes the cases which showed no skeletal involvement but demonstrated renal calculi. Disease of the bone was demonstrable in 67 per cent of the author's cases. However renal calculi and calcification were found in 93 per cent of the cases. Classic bone disease seemed to be slightly more frequent in women than in men, whereas renal disease was more frequent in men.

Symptoms of hyperparathyroidism were divisible into three groups in accordance with the chemical changes in the blood and urine, or the degree of involvement of the kidneys or of the skeletal system. Chemical changes in the blood were manifested by an increase of calcium and a decrease of inorganic phosphorus. As a result the symptoms were muscular atony, weakness, fatigue and constipation, all of which could be correlated with the degree of hypercalcemia. Polyuria was present in 46 per cent of the cases and was regarded as being due to the excessive excretion of calcium and phosphorus. The latter also provided the basis for nephrocalcinosis. Hyperparathyroidism was suspected in any patient having renal calculi of calcium. Laboratory diagnosis was made on the basis of increased calcium and decreased phosphorus in the serum with a loss of calcium in the urine. Repeated blood determinations were necessary since the elevation of calcium was slight. Thus, in 12 of the 24 cases of hyperparathyroidism the blood calcium averaged less than 12.5 mgm. per cent. Ionic calcium was found to be specifically affected by parathyroid disease while

the organic calcium proteinate was not so influenced. With multiple myeloma or sarcoidosis there was a secondary hypercalcemia mainly in the organic fraction of the blood which accompanied a hyperproteinemia. When the value of serum calcium was equivocal, a low level of inorganic phosphorus, below 3.5 mgm per cent, served as a good diagnostic clue. Elevation of the alkaline phosphatase was useful as an indication only of bone disease but not necessarily of hyperparathyroidism. Under properly controlled dietetic conditions a strongly positive Sulkowitch test for calcinuria was supportive of the diagnosis of hyperparathyroidism. With the Bauer and Aub diet normal persons excreted less than 100 mgm. of calcium whereas hyperparathyroid patients lost between 125 and 200 mgm. per day. In groups 1 and 2 demineralization of the skeleton was manifested by pathological fractures, multiple bone cysts, and milary osteoporosis of the skull. Dental roentgenograms were significant when in conjunction with other bone changes disappearance of the lamina dura of the teeth was found. Examination of renal calculi caused by hyperparathyroidism showed a predominance of calcium oxalate.

In all of the 24 cases a parathyroid adenoma was demonstrated at operation. In no case was a diffuse adenomatosis of all parathyroid tissue found. None of the adenomas in this series was in the mediastinum and none was considered malignant. After operative removal, the blood calcium and inorganic phosphorus returned to normal the former within two days and the latter more slowly. In 50 per cent of the patients tetany ranging from mild to severe, developed postoperatively. Severe tetany seemed to occur most frequently in those cases which exhibited extensive osseous change and high levels of alkaline phosphatase. Mild tetany was accounted for on the basis of a reverse shift in the calcium and

Fig. 1. The changes in the average level of calcium in serum before and after removal of a parathyroid tumor. Each point represents the average of numerous determinations made, in most instances, over a period of several weeks. In 1 case in group 3 no significant change in serum calcium occurred following the operation. The level of inorganic phosphorus and the excretion of calcium were also unchanged, and this has been assumed to indicate that a second tumor is probably present.

phosphorus which created a temporary period of hypoparathyroidism. B G P SHAPIROFF M.D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Sunderland, S.: Traumatic Injuries of Peripheral Nerves; An Analysis of the Incidence in 301 Consecutive Cases of Peripheral Nerve Injuries. *Austral N Zealand J Surg* 1945 15 25.

The author presents a statistical summary of 301 consecutive cases of peripheral nerve injuries observed in military centers in Australia, during the period from 1941 to 1944. The data, summarized mainly in several charts, give the incidence of injury according to the cause ([1] gunshot wounds of war and [2] lesions due to other causes), the location of the injury as to nerve or combinations of nerves, whether the injury was right or left-sided and whether the injury was complicated by bone injury as well. It was found that plexus injuries predominated on the left, that lesions of the ulnar nerve occurred twice as often as those of the median or radial nerves which were involved in approximately equal proportions and that in combined lesions the radial, median and ulnar nerves were affected in equal proportions. In upper limb injuries single nerve lesions outnumbered combined nerve lesions 6 to 1 and upper limb injuries were three times as numerous as those in the leg. Gunshot wounds of the sciatic nerve were nine times as numerous as those due to other causes. In the gunshot injuries lesions of the ulnar nerve predominated also; this nerve was more frequently the common factor in combined lesions than either the radial or median nerve. The commonest cause of peroneal nerve injury was the pressure of a plaster cast.

JOHN MARTIN, M.D.

Sunderland, S.: Blood Supply of the Sciatic Nerve and Its Popliteal Divisions in Man. *Arch. Neurol. Psychiat.*, Chic., 1945 54 283.

The author studied in considerable detail the gross and microscopic characteristics of the vascular patterns of the sciatic nerve in 40 adult human cadavers, with special attention to the gluteal region, the upper middle and distal thirds of the thigh, the popliteal fossa, the neck of the fibula, and the upper middle and distal thirds of the lower portion of the leg. He found that the largest arteries nervorum of the entire body were those supplying the sciatic nerve in the buttock and thigh (Fig. 1). They were arterioles, and they arose from the inferior gluteal artery and the perforating anastomotic chain. Nutrient arteries of the direct type predominated, and these occurred in a T-pattern most commonly when they reached the nerve. The large nutrient vessels were found to enter the nerve directly in most cases, without a long superficial course in the upper sciatic nerve. In the popliteal fossa the largest vessels ran on or within the nerve, but as the common peroneal nerve approached the

Fig. 1. Illustration of a dissection, showing the blood supply to the sciatic nerve from the inferior gluteal artery, crucial anastomosis, and, in particular, the perforating anastomotic chain. The nerve has been displaced medially to demonstrate the latter.

neck of the fibula the larger intraneural vessels were found to occupy a superficial and exposed position in 88 per cent of the specimens, and a deep and protected position between nerve fasciculi in only 12 per cent.

Not only is the peroneal nerve a smaller and less well protected nerve than the tibial, which might partially account for its susceptibility to pressure effects but it is also usually in the form of one major bundle so that its vessels have poor protection from outside pressure. Furthermore the peroneal nerve is poor in supporting and protective adipose tissue. The tibial arteries nervorum have the added protection that they lie in crevices between several bundles of the nerve.

An excellent table is provided to show the source and number of the nutrient arteries to the sciatic nerve in man.

JOHN MARTIN, M.D.

Barnes, R., Bacsich, P., and Wyburn, G. M.: A Histological Study of a Proneurogenic Nerve Autograft. *Brit. J. Surg* 1945 33 130.

For purely investigative purposes, the authors performed an autograft in a patient with a large and irreparable injury to the ulnar nerve. Seven centi-

SURGERY OF THE NERVOUS SYSTEM

meters of the distal segment of the nerve were excised, and were then sutured to the freshened distal end of the proximal segment. The graft was 3 millimeters in diameter and the central segment was 6 millimeters in diameter so that contact of only about 25 per cent was obtained between the stump and the graft. Three fine linen thread sutures were passed through the sheath of the nerve to effect this contact, and the distal end of the graft was then sutured to the intermuscular septum. There was little or no scarring of the soft tissues in the new graft bed. This operation was performed 613 days after the original injury.

After an interval of 168 days the wound was again opened and the graft inspected. There was firm healing at the line of suture and at that point there was a firm fusiform swelling of the nerve. The graft was firmer than at the time of insertion and it was not unduly adherent to the surrounding tissues. The graft was then stimulated with the faradic current (this operation having been done under local anesthesia) but no sensory response was obtained distal to a point 1 cm below the suture line. The entire graft together with 2 cm of the central stump was then removed for histological study.

This autograft was found not to have undergone any central necrosis, and it had provided a pathway for new nerve fibers some of which were found to have proceeded for 20 mm beyond the suture line. None of these new fibers were medullated and the transition from medullated to nonmedullated character took place abruptly and immediately above the suture line. In the opinion of the authors this absence of medullation may have been due to extensive intrafascicular fibrosis which prevented normal maturation of the nerve fibers. While the new nerve fibers in the graft were neither normal in anatomy or quantity it was of significance to the authors that such an old predegenerated autograft could receive nerve fibers after so long a time and that a central stump still could retain regenerative powers as long as 613 days after the original injury.

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Murphy J P and Gellhorn E.: Multiplicity of Representation Versus Punctate Localization in the Motor Cortex; An Experimental Investigation. *Arch. New Psychiat. Chic.*, 1945 54 256

This report of an obviously carefully worked out investigation indicates that there is a multiplicity of motor representation in the cerebral cortex rather than the commonly conceived restricted localization of motor function. In the words of the authors emphasis is shifted from isolated cortical representation to more inclusive cortical function.

The animals employed in the study were the rabbit, cat, and monkey these animals being chosen to determine whether or not results of cortical stimu-

lation executed after an original concept of the authors, could be correlated with the principle of progressive encephalization. Such correlation was in fact, possible but to a limited degree, and the broad concept of multiple cortical representation was found to be maintained in this admittedly limited phylogenetic arc.

The authors believe that in stimulating the cortex it should not be subjected to the weakest possible electrical currents but that the aim should be to evoke as much as possible of the total capacity for physiological response. Under such conditions of cortical stimulation they found that multiple representation of movement is widespread in the motor cortex of the rabbit, cat and monkey and that the most common type of multiple representation is that found in the large somatotopic divisions of the leg arm and face. The cortical overlap of two large somatotopic subdivisions apparently decreases with progressive encephalization as the phylogenetic scale is ascended. The point is made that it is movements not muscles which are much more widely represented than the usual cortical maps would indicate. Movements involving distal joints were not found to be more widely distributed than movements involving the proximal joints.

The authors believe that this multiplicity of representation and the extent of representation of movements beyond the bounds ordinarily determined by threshold stimulation probably account for the recovery of function of individual parts of the body after contralateral cortical tissue has supposedly been removed.

JOHN MARTIN M.D.

Oldberg S.: The Significance of Internal Frontal Hyperostosis and Some Related Changes of the Skeleton with Special Reference to Diabetes in the Aged (Ueber die Bedeutung der Hyperostosis frontalis interna und einiger verwandter Skelettveränderungen unter besonderer Berücksichtigung der Verhältnisse bei Altersdiabetes). *Uppsala Lak. Soc. Jark* 1945 51 1

During the last decades the cranial change, which for a long time has been called hyperostosis frontalis interna, has aroused an increasing interest from the clinical as well as from the pathological-anatomical point of view. Under the more comprehensive names "hypophyseal cranial dysplasia" or "metabolic cranio-pathy," a more diffuse thickening of the calvaria is found. While the afore mentioned endocrine origin of local frontal hyperostosis has been generally accepted the genesis of diffuse hyperostosis is less clear and an association between both forms has not been proved. Certain bony changes which have been assigned to the normal increase of age, the so-called senile hyperostosis, have been of great importance in the subject under discussion. The occurrence of the last mentioned change has been considered self-evident for at least 100 years but systematic investigation has not been made.

The clinical significance of the cranial changes is not clear. They have been included together with

adiposity and certain psychoneurological symptoms in the so-called Stewart Morel syndrome and with adiposity and virilism in the Morgagni syndrome. Some authors have emphasized that in case of local frontal hyperostosis a disorder in the carbohydrate metabolism in the diabetic sense may occur. The suggestion has been advanced that by confirming this bone formation an opportunity is afforded for diagnosing pituitary diabetes. The circumstances, however, are not cleared up and no research has been made on a larger scale.

From his x ray studies the author has tried to find out the appearance of the normal calvaria at different ages. The occurrence of the local frontal hyperostosis as well as the general thickness was observed, being directly measured on the x ray plate at certain points. The results thus obtained were taken as a starting point and the same investigation was carried out on material consisting of selected cases of local frontal hyperostosis, acromegaly, hypophyseal adenoma, operatively verified, and also a number of cases of senile diabetes. The author tried to clarify the so-called senile hyperostosis and the hypophyseal genesis of the diffuse thickening of the skull, and, by measuring the sagittal diameter of the atlas, tried to get a clear idea of the relationship of localized changes of the skull to more general disturbances in growth. By means of a comparison between cases with and without frontal hyperostosis and the diffuse thickening of the calvaria, respectively, the author tried to find evidence for the clinical significance of these bone changes. Special interest was taken in the possibility of classifying the cases of so-called senile diabetes in two genetically different forms.

The result of the investigation can be summarized as follows:

1. Signs for the so-called senile hyperostosis are lacking.

2. Hyperostosis frontalis interna appears almost exclusively in female patients, usually first after the menopause, and increases in frequency with age. The endocrine disorder in these patients manifests itself furthermore in a delayed menopause.

3. The general thickness of the calvaria can be attributed directly to a disturbance in growth of hypophyseal origin. It is most pronounced with acromegaly and a little less pronounced with chromophilic hypophyseal adenoma without acromegalic signs, whereas in the case of chromophobic adenoma the thickness is about normal, but still shows some difference.

4. Hyperostosis frontalis interna is positively correlated with a diffuse thickening of the os parietale and consequently with the diffuse thickening of the calvaria. Accordingly it often occurs in cases of acromegaly.

5. In cases of acromegaly as well as of local frontal hyperostosis there is furthermore, an enlargement of the sagittal diameter of the atlas. Thus, there exists an association among hyperostosis frontalis interna, the diffuse thickening of the calvaria and

the enlargement of the atlas, which must be considered as a general growth tendency in the skeleton. The hypophyseal genesis of this bone change is discussed.

6. Hyperostosis frontalis interna and, to a certain extent, the general thickening of the calvaria are in a co-ordinative relation with adiposity, dizziness, and probably with headaches. Therefore, the term "Stewart Morel syndrome" seems to be justified. On the contrary there is no relationship between the above named bone change and hypertrichosis, therefore the term "Morgagni syndrome" seems to be inadequate. The occurrence of dizziness and headaches does not correspond to an increase in the blood pressure. In the diagnosis of adiposity in its different forms the aforementioned bone changes seem to point to a hypophyseal origin.

7. The occurrence of local frontal hyperostosis and to a certain degree even that of the diffuse thickening of the calvaria in women as well as in men, suggests the possibility of an extralobular diabetes of hypophyseal origin when the diabetes presents (a) a benign course not infrequently with spontaneous remission, (b) a slight acidotic tendency and thus an inconsiderable risk of coma, (c) a requirement of insulin only in a few cases, exclusively those of persons who have been ill for several years and (d) a decrease in sensitivity to insulin.

8. The occurrence of hyperfunction of the anterior lobe of the pituitary gland, especially in women after the menopause (formerly chiefly recognized by an increased excretion of gonadotropic hormone) includes even a growth promotive factor and probably also a diabetic one. The practical value of the above mentioned changes of the skeleton as an easily diagnosed clinical sign for hyperpituitarism is emphasized.

Davidson, C. and Demuth, E. L.: Disturbances in Sleep Mechanism: A Clinicopathologic Study. Lesions at the Corticodiencephalic Level. *Arch. V. or Psychiat. Chic.*, 1935 54 232

Discrete lesions of the hypothalamus are known to cause interference with the normal physiological regulation of sleep and all the available clinical evidence indicates that lesions at the corticodiencephalic level not uncommonly produce pathological sleep as well. The authors have had 35 patients with such pathological sleep syndromes. In all, either the cortex or the diencephalon, or both, were involved. Twenty-one patients suffered neoplastic disease, and the 4 other patients had brain abscess, encephalitis lethargica, diffuse syphilitic disease and vascular disease. A strikingly high percentage of the patients showed clearly an extensive change in the hypothalamus. This structure showed compression changes in 16 cases, actual invasion in 4 cases, and gross destruction in 1 case. In 3 patients however the hypothalamus, though compressed did not show any change in the nerve cells. Also, in 16 patients there was in addition to the changes in the hypothalamus, compression or invasion of the basal ganglia with implication of the striohypothalamic pathways. Inas-

much as most of the neoplasms in the series were found to have encroached upon the ventricular system a high incidence (18 patients) of increased intracranial pressure was present in this series.

In a previous article the authors expressed the opinion that some fibers for the control of sleep were believed to originate in the cerebral cortex especially the hippocampal, angular frontal, premotor and temporal convolutions. On the basis of the 25 case histories reviewed in the present article, they postulate that the following structures (both afferent and efferent in nature) are concerned with sleep regulation: the medial forebrain bundle running between the ventromedial olfactory correlation areas of the cortex and the preoptic and hypothalamic areas; the corticohypothalamic fibers via the fornix, the inferior thalamic peduncle and a postulated hypothalamocortical tract. JOHN MARTIN M.D.

Bucy, P. C. Surgical Relief of Tremor at Rest
Ann. Surg., 1945 122 933

A case report is made of a 23 year old male with a diagnosis of unilateral Parkinson's syndrome on the right side following chronic encephalitis the onset of which apparently took place at the age of 5½ years. The patient showed marked unilateral tremor, a weakness of the right lower extremity of slight degree and possibly some weakness of the right upper extremity.

Operation was performed, the central sector of the cortex of the left cerebral hemisphere was exposed up to the midline, with the fissure of Rolando in the middle of the operative field. The cortex did not appear abnormal. All of the exposed cortex was electrically stimulated following which the posterior half of the precentral gyrus was removed over the area which had caused movement (by stimulation) in the right upper and lower extremities. The area was resected subpially down to the bottom of the central sulcus. The great rolandic vein and the communicating vein which crossed the region of extirpation were left intact.

Following operation, the patient had complete paralysis of the right upper extremity and marked weakness of the right lower extremity. There was

gradual improvement in function of the right side without evidence of a return of the tremor.

The last report (9 months after operation) stated that the patient was able to walk with his body upright, rather than with a hemiparetic gait. The tendon reflexes were increased on the right side although this had been true preoperatively. There was no evidence of return of the tremor up to that time.

The area extirpated was the arm and leg portion of area 4 Y and according to the author such extirpation can be expected to abolish tremor at rest in the contralateral upper and lower extremities. The procedure may be expected to produce some increased spasticity and increased perspiration over the right half of the body for a few days. No sensory alterations were noted. HOWARD A. BROWN M.D.

Bailey, P.: Chronic Leptomenigeal Thickening following Treatment of Meningitis with Sulfadiazine. *Ann. Surg.*, 1945 122 917

Four cases of meningitis are reported which were treated with sulfa drugs or penicillin. These cases demonstrated the sequelae which may occur despite the use of these drugs. In all 4 cases the acute purulent infection was controlled but despite this the condition went on to death or a serious sequel because of the fact that the drugs exert no restraining influence on the fibroblasts which proliferate rapidly in an attempt to organize the exudate.

As a result of these changes the leptomeninges become densely scarred and prevent the normal circulation of cerebrospinal fluid. There also may be constriction of the blood vessels as a result of the same pathological process.

The author intends to call attention to the dangers that may arise as a result of these alterations in the nervous system, although early optimism may arise immediately following the administration of these drugs in the treatment of purulent meningitis.

It is not his contention that the drugs should not be used but he states that early diagnosis and intensive therapy with adequate doses before massive exudate has occurred may be of value in preventing these changes and improving the prognosis.

HOWARD A. BROWN M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Spalding, J. E.: Adenolipoma and Lipoma of the Breast. *Gw's Hosp Rep Lond.* 945 94 80.

The author reports the case of a 56 year old woman who had noted a swelling of the left breast for one year. Since she first noticed the swelling the breast had steadily enlarged. Examination of the breast revealed a lump 8 cm in diameter immediately lateral to the areola. The mass was spherical, well defined and freely movable within the breast. The axillary lymph nodes were not enlarged. The breast was amputated.

The tumor mass was well defined. Microscopically the tumor consisted of fat tissue with islands of epithelium embedded in the fat. In the central part of the tumor there were large islands of epithelial tissue in which alveoli, alveolar ducts and larger ducts could be distinguished.

The author considers this to be not a pure lipoma but rather an adenolipoma. He described a lipomas of the breast that are in the Gordon Museum.

EARL O. LATIMER, M.D.

TRACHEA, LUNGS, AND PLEURA

Clark, D., and Gilmore, J. H.: A Study of 144 Cases with a Positive Coccidioidin Skin Test. *Ann. Int. M.* 1946 24:140.

One or more coccidioidin intracutaneous tests were made on 373 patients, and from 125 with a positive reaction, 100 with residual roentgenographic findings in the lungs were chosen for study, analysis and report. This investigation was made in the pulmonary section of an Army General Hospital serving the southwestern part of the United States in 1942.

The fungus *Coccidioides immitis* is found in arid soil, and has been isolated from wild rodents in central and southern California, Arizona, New Mexico and West Texas. The organism is diphasic, occurring in animal tissue as a spherule from 1-60 microns in diameter with a doubly refractile wall, and multiplying by endosporeulation.

The earliest pathological lesion in man as surmised from studies on animals, is an infectious granuloma following the inhalation of infected dust or, more rarely, entrance through a lesion in the skin. The infection is usually mild, self limited and involves the lungs and associated mediastinal lymph nodes. Antibodies develop in the blood and the lesion disappears or fibrosis leaves a rounded or linear scar and solid immunity. Reinfection does not occur. Exceptionally an abscess may form in the lung or pleura and heal by absorption and fibrosis, or it may break down and discharge organisms through a bronchus which appear in the sputum for months or years without causing sec-

ondary lesions. Rarely chiefly in individuals of the dark skinned races, the infection gains entrance to the blood stream and causes death. In survivors, granulomas appear throughout the body. These tumors may be slowly absorbed or may form chronic abscesses.

The differential diagnosis included tuberculosis, residual pneumonitis fibrosis, healed septic abscess, bronchitis bronchiectasis Boeck's sarcoid and metastatic malignancy. Attention was paid to residence in areas endemic for coccidioides skin tests for coccidioidin and tuberculin, the sedimentation rate, sputum study of the blood for coccidioidin antibodies and roentgenographic examination of the chest.

Fifty-two patients had fever, mild chills, cough, occasional slight hemoptysis, small amounts of mucoid sputum, chest pain, and malaise. Four had skin manifestations. Evaluation of the lungs could not be made without roentgenograms, although pleurisy pleurisy with effusion, and pneumonitis secondary to coccidioidin infection were sometimes found on physical examination.

Coccidioidomycosis mimics tuberculosis however superinfection or the adult type of pulmonary tuberculosis is not characterized by hilar or mediastinal adenopathy. Roentgenographic findings may be grouped under five major types: (1) with pneumonialike infiltrations (2) with tracheobronchial mediastinal or hilar adenopathy or a combination of both (3) discrete nodular type with a round or oval area of increased density from 1 or 3 to 10 mm in diameter occasionally calcified (4) with annular shadows having thick walls and (5) with upper lobe granular or with slightly nodular infiltrations with extension of linear markings into the hilum. As healing takes place initial pneumonialike infiltration is followed in some cases by complete disappearance of the lesion, in others by nodular lesions, by annular lesions, or by strandlike infiltrations.

Many individuals who have been in southwestern United States show a positive reaction to the coccidioidin skin test, and some of these show roentgenographically persistent areas of increased density in the lungs which can be disregarded as a cause of future illness or disability if they are due to an inactive coccidioidin infection but they must be distinguished from tuberculosis and more rarely other potentially dangerous diseases.

A lung lesion absent in previous chest films but present some time after an individual was on the desert is probably due to coccidioidomycosis. Coccidioidin in concentrated form for skin testing in a 1:100 dilution with normal saline solution was obtained from Charles C. Smith of the Department of Public Health, Stanford University.

LYNN JOHNSON, M.D.

SURGERY OF THE THORAX

Camaner A: Cancer of the Lung with Initial Neurological Symptoms (Cáncer de pulmón con síntomas iniciales neurológicos) *Rev As méd. argent.*, 1945 59 1088.

Following a brief discussion of the many syndromes due to pressure on the peripheral and central nervous systems by the growth of the metastases of pulmonary tumors the author notes that in the material at the Hospital Rawson in Buenos Aires the most common form of pulmonary tumor is silent and announces itself as a hemiplegia with a progressive subacute course with localization of the metastases at the level of the internal capsule, in the subcortical area, or in the ascending growth then tends to invade the cortex in this area producing the Bravais-Jacksonian type of epilepsy and later the other structures of the brain particularly the basal nuclei and ventricles and leads to an early death. There is a relatively late appearance of evidence of intracranial pressure, the demise being due rather to the interruption of the vital nerve impulses from the central nuclei.

The article concludes with 4 typical case histories, all in males from 34 to 66 years of age. In each case the hemiplegia was on the left side, progressing rapidly to complete paralysis of the left arm and leg and in no case was any evidence of lung involvement observed until the x rays were used. By this means an original new growth was discovered at the hilus of the right lung in 1 patient, at the right vertex and base respectively, in 2 patients, and at the vertex of the left lung in the last patient.

JOHN W. BARKMAN M D

Strieder J W and Lynch J P Putrid Empyema. *N England J M* 1946 234 1

A better understanding of putrid empyema to be distinguished by surgeons from pyogenic empyema will bring prompt recognition adequate treatment and lowered mortality. An analysis of 90 cases at the Boston City Hospital Boston Massachusetts from June, 1934 to January 1941 and of specific cases subjected to thoracic surgery between January 1938 and January 1941 demonstrates the advantages of early radical surgery.

Putrid empyema a sloughing gangrenous pleuritis, is caused by anaerobic bacteria in symbiosis and characterized by purulent foul, sulfurous or putrid pleural fluid and often gas. From 5 to 10 per cent of 530 cases of empyema treated at the Boston City Hospital in 7 1/2 years were putrid.

Putrid empyema complicated lung abscess gangrenous fusospirochetal pneumonia bronchiectasis tuberculosis with secondarily infected blocked cavities which ruptured into the pleura, pulmonary gangrene distal to obstructing carcinoma, and trauma. The acute stage of all putrid pulmonary infections is believed to be pneumonia.

Gushed from pneumococcal pneumonia was pneumonia. The clinical impression on admission was pneumonia. The physical signs were those of fluid roentgenograms showed consolidation even when fluid

was present. A history of foul sputum was diagnostically helpful. The patients early became toxic and delirious and showed signs of peripheral vascular collapse and the pulse was elevated out of all proportion to the temperature a feature common to all anaerobic infections.

Thoracentesis fluid with a foul odor was pathognomonic. Direct smear revealed fusospirochetes. Anaerobic culture of the pleural fluid demonstrated infection in which symbiosis was involved and related to the antecedent disease. Vincent's angina, periodontal infection, and pyorrhea alveolaris were common in the patients from whom the organisms were aspirated. The infections are referred to as fusospirochetal but anaerobic cocci are associated with them and are of equal importance.

Common to all anaerobes is their inability to live or multiply in an atmosphere rich in oxygen. Consequently open operation with adequate aeration and evacuation of the pus is the treatment of choice. Despite the consistency of the fluid there is prompt stabilization of the mediastinum.

If this is inadequate the pleura is widely incised for about 20 cm. A large prepared dressing is applied and the patient is quickly turned on his back. The dressing becomes saturated and serves as a tampon preventing air exchange while the large wound allows complete drainage. A quick change of dressing is made during expiration the third day. Stabilization occurs from the fifth to the seventh day. A gauze pack impregnated with activated zinc peroxide placed partly in the pleural cavity and partly in the wound controls odor and the wound is clean and granulating in from 5 to 7 days, when the tubes are inserted for convalescent care.

Sulfonamides and arsenicals are of no benefit, but penicillin is a valuable adjunct and effects cures in a certain percentage of cases. Recovery is greatest with early operation. Seventy five per cent of the patients operated upon in the first week recovered. Only 1 patient lived when the disease had persisted 10 days before operation. The surgical treatment generally given for postpneumonic empyema was not adequate for putrid empyema. The mortality under such conditions was 54 per cent. Three deaths among the 21 patients recovering from open resection indicate that a fatal outcome in spite of adequate surgical treatment is usually due to the primary disease. The results obtained demonstrate the benefit of immediate surgery of the open type. The use of activated zinc peroxide packs is specifically helpful.

LYNN JOHNSON M D

HEART AND PERICARDIUM

Blanchi A E., and Rapaport, M: Sarcoma of the Right Auricle (Sarcoma de la aurícula derecha) *Arch. Soc. argent. anal normal B* 1945 6 321

The author describes a primary sarcoma of the right auricle of fusocellular type which formed numerous metastases in the lungs and showed a rapid evolution.

INTERNATIONAL ABSTRACT OF SURGERY

He also collected 34 cases of sarcoma of the right auricle from the literature. Histologically the growths were formed by giant, round or polymorphic cells a few of the growths were fibrosarcomas and fusocellular sarcomas. One was a fibroblastic sarcoma and one a leiomyosarcoma.

In regard to the mode of growth, four types of auricular blastomas may be differentiated: (1) those of an infiltrating character only partially obstructing the auricular cavity (2) those growing exuberantly filling the cardiac cavity and transforming it, as in the authors' patient, into a narrow canal, (3) those affecting chiefly the superior vena cava, and (4) those infiltrating chiefly the myocardium.

Among 35 cases collected from the literature by the authors metastases were found in the lungs in 12 cases in the heart in 10 cases in the mediastinal glands in 7 cases, in the liver in 3 cases and in the pericardium in 3 cases, while the suprarenal glands, inferior vena cava, pancreas and pleura were less frequently the sites of secondary growths. In numerous instances multiple metastases were present, but no metastasis was found in 12 patients.

The authors' patient was a woman 30 years of age who developed dyspnea and an enlargement of the heart 6 months prior to her admission to the hospital. Auscultation failed to reveal any valvular lesions. Gradually an edema of the left upper extremity and of the left side of the chest developed and a considerable enlargement of the liver was noticed. Hemoptysis and edema of the lumbar region and of the lower extremity gradually appeared. No tubercle bacilli were found in the pleural exudate. The fever was of a recurrent type.

The autopsy revealed a sarcoma of the right auricle with metastases in the pleura and the lungs fibroplastic pericarditis and dilatation of the heart.

MISCELLANEOUS

Ratzan, M. C., and Thompson, S. A.: Hypoproteinemia in Surgery of the Thorax. *Am. J. Surg.* 1945 70 213.

Hypoproteinemia in patients with intrathoracic disease is insidious in onset and course, progressive in character and dangerous. Clinically a total protein value of below 5 gm. per cent will find healing markedly impeded. As the percentage is lowered the percentage of fascial planes, herniation, and eversion occur. The cardiorespiratory dysfunction attendant upon a total protein value of below 5 gm. per cent, and an albumin value of below 3.5 gm. per cent will yield a final anasarca.

The balance of protein is obtained through the interplay of 4 factors (1) the exogenous source (food) (2) the synthesis of albumin, globulin, and fibrinogen by the liver after protein breakdown and amino acid splitting (3) loss of protein through increased metabolism and continued inflammation (effusion and empyema) and (4) the excretion, mainly urinary albumin. In thoracic surgery all of these factors are abnormal.

The lowering of the plasma protein in cases requiring thoracic surgery is largely dependent upon the intrapleural condition. It is also moderated by the extent, type and severity of the operative procedure.

The use of blood transfusions, plasma and amino acids by mouth or parenterally must be employed to augment protein intake when excessive postoperative protein depletion is anticipated. The most economical protein replenishment is obtained by the intravenous or intramedullary use of amino acids either the acid hydrolysate with tryptophan or the enzymic digest are suitable for this purpose.

SAMUEL KATZ, M.D.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Fernandes, O: Roentgenological and Clinical Study of Duodenal Stasis (Estado radiológico e clínico das estases duodenais) *Brasil med chirg* 1945 7 355

After presenting a short review of the embryological development of the duodenum, the author offers the following classification of duodenal obstruction.

A. Intrinsic lesions (1) congenital partial or total absence of fixation with abnormal mobility and diverticulum, (2) acquired diverticula, bridges, adhesions, modification of the mucosa hypertrophy of the muscular layers ulcers tumors, and foreign bodies.

B. Extrinsic lesions compression by tumor and compression by a pedicle of the mesentery

C. Functional lesions spastic conditions hypotonia and atony

A mobile first portion of the duodenum may form a fistoon and cause obstruction. In other cases only the portion just above or immediately below Vater's papilla is abnormally mobile and in another variety of mobile duodenum only the third portion is involved. A total mobile duodenum is a rare malformation making up a part of the anomaly called common mesentery.

A diverticulum may be located at the duodenojejunal junction or higher up. Diverticulitis may be the sequel of duodenitis. An acquired diverticulum may form above a stenosis and results from a lack of equilibrium between the duodenal contents and the resistance of the wall.

Bridges, bands and adhesions usually are the result of chronic adhesive peritonitis. Hereditary syphilis tuberculosis, cholelithiasis, and other con-

ditions may produce an inflammatory periduodenitis. Similar processes may follow more distant infectious conditions located in the pelvis or around the appendix.

Intensive duodenitis may spread to the submucosa and cause a hypotonus accompanied by a diminished peristalsis which leads to stasis. Hypertrophy of the valvulae conniventes may also cause stasis. Hypertrophy of the muscular layer may lead to the formation of a veritable sphincter.

Ulcers may be caused by or provoke the occurrence of stasis because of adhesions and cicatricial stenosis. Irritation of the mucosa by violent peristaltic and antiperistaltic motions and trauma of the epithelium in the presence of stasis may cause the formation of an ulcer. Among benign tumors causing stasis the following may be mentioned adenoma fibroma lipoma, myoma, and hemangioma. Such tumors may be sessile or pedunculated. Malignant tumors such as carcinoma, fusocellular sarcoma, myxosarcoma, and melanomasarcoma are rare in this condition.

As to foreign bodies gallstones are the most frequent.

A ptosis of the anterior branch of the vascular mesenteric pedicle may cause a pinching of the third portion of the duodenum. Two arteries may compress the anterior aspect of the duodenum, namely the superior mesenteric and the middle colic arteries.

A chronic duodenal stasis is characterized by the following signs: a rise of nonprotein nitrogen in the blood, an increase of the alkaline reserve, a considerable fall of the blood chlorides, an intensified nitrogen excretion in the urine, a diminution of chlorides in the urine, and hyperpolypeptidemia.

Golden, R., and Ducharme, P.: The Clinical Significance of Deformity of the Cecum in Amebiasis. *Radiology* 1945 45 505

Because several cases were encountered at Presbyterian Hospital, New York City in which the first suggestion that amebiasis was present came from the demonstration of a deformed cecum the authors undertook a review of the records of the 119 cases observed at this hospital in which amebiasis was either proved or thought to be present. In 108 of these cases the endamoeba histolytica was recovered either from stools or tissues. In several of the remaining cases only one stool had been examined.

The cases were grouped into (a) 61 with diarrhea, (b) 15 with abdominal pain without diarrhea, (c) 34 with no significant symptoms directly referable to the intestinal tract, and (d) 9 in which there was inadequate information in regard to abdominal pain. Barium examination was done in 33 of the cases with diarrhea, of which 18 showed a deformed cecum among the 9 cases with abdominal pain a cecal deformity was demonstrated in 3 among the 18 in group c a cecal deformity was found in 4, and among the 7 cases in group d a deformed cecum was discovered in 5. Hence, of the 67 cases subjected to colonic barium study 30 (45%) showed a cecal deformity and this finding occurred 5 times as frequently in cases with diarrhea or abdominal pain as in cases without such symptoms. In 53 of this group of 67 the endamoeba histolytica was demonstrated in the stools and its presence was not disproved in the other 9. Of these 53 cases 41 (36%) showed cecal deformity while another case with deformed cecum and ascending colon terminated in clinical recovery only after a course of emetine. Two other cases of proved amebiasis showed deformity of the transverse colon and a third revealed rectal stricture. Hence approximately 50 per cent of the patients examined and 41 per cent of those with endamoeba histolytica in their stools had definitely abnormal roentgen findings 90 per cent of these deformities were of the cecum. In only 3 cases showing a deformed cecum was there also an associated deformity of the more distal colon but in none of the cases was the terminal ileum narrowed or intrinsically distorted.

In the majority of cases of deformed cecum, the cecal outline was smooth, and in a few irregular. The deformity to be significant, should be persistent in some degree throughout the examination. In 4 of the 5 cases re-examined after therapy for amebiasis some decrease of the deformity was noted but in the fifth case in which shrinkage was extreme no change resulted. The authors believe that at least a portion of the reversible change is due to cecal spasm.

As regards the differential diagnosis the authors point out (1) that in the large majority of cases tuberculosis involves both the cecum and ileum although hyperplastic tuberculosis of the cecum could simulate the deformity described above (2) that regional ileitis commonly involves the ileum

often with resultant narrowing and irregularity of the terminal portion, but it attacks the cecum much less commonly (3) that carcinoma of the cecum usually produces an irregular asymmetrical filling defect often associated with a palpable mass quite different from the usually smooth walled contracted cecum of amebiasis but, of course should a mass be formed by a large amebic granuloma, it could not be distinguished roentgenologically from carcinoma.

The authors conclude that recognizable deformity of the cecum without involvement of the terminal ileum is likely to be present in more than a third of the cases of amebiasis and that this deformity is a clinically valuable sign not diagnostic, but definitely suggestive of the disease. Its absence, on the other hand is of no value in ruling out the disease.

ITALIAN DONALDSON, M.D.

Clute, H. M., and Kenney F. R.: Primary Anastomosis in Carcinoma of the Colon. *England J. M.*, 1945 33 790.

Sixty five cases of carcinoma of the colon are reviewed. The total mortality was 18 per cent (8 deaths) in 34 cases with resection and immediate anastomosis there was a single death, or a mortality of 3 per cent. Eighteen cases requiring Mikulicz resection had a 4 per cent mortality (1 death) Seventeen inoperable cases upon which only palliative procedures could be done had a mortality of 29 per cent (5 deaths) Of the deaths among the resectable cases, 1 was due to shock, 1 to coronary thrombosis and 1 to pulmonary embolism.

These cases evaluate the feasibility of immediate restoration of the intestinal continuity following radical resection of carcinoma of the colon. The authors intended to evaluate the use of chemotherapy in the improvement of their results but became impressed by the numerous factors that had improved colon surgery. They emphasize the value of preoperative and postoperative care. The treatment of anemia and protein deficiencies is accomplished with adequate quantities of blood and the intravenous administration of amino acids before and after surgery. The authors value the use of sulfasuxidine in the preoperative reduction of intestinal flora and because of its mild laxative effect, but note that cases in which it was not used presented equally good results in many instances. They have discontinued the preoperative use of drastic purgatives. Gastric suction is advised for a day before operation and is continued postoperatively until the return of normal peristalsis.

The authors favor radical removal of the tumor and of the lymph glands draining the involved segment of colon. The Mikulicz and other obstructive resections have been relegated to cases in which the risk is poor with partial obstruction or some degree of infection because they can be done quickly and the bowel is simultaneously decompressed. Resection and immediate anastomosis are preferred because of the many advantages to the patient, such as the elimination of spur crushing and of the an

noyances associated with a colostomy. Primary anastomosis has not increased the mortality. The authors did not use many cecostomies but believe that cecostomy is a worthwhile procedure to protect the anastomoses distal to it in the colon and to decompress the obstructed colon which eliminates the necessity of resection for the obstruction.

The article presents the advances made in colonic resection in the last few years, particularly since the introduction of drugs reducing the incidence of infection and the greater knowledge of fluid balance and of total nutrition of the surgical patient.

FREDERICK C. HOBEL, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

With, T. K.: On the Occurrence in Human Serum of Yellow Substances Different from Bilirubin and Carotenoids. *Acta med scand* 1945 132 501

The author has described a method for the quantitative estimation of the nonbilirubin yellow substance in serum by means of the Pulfrich photometer. Investigation of the spectral absorption of pure solutions of bilirubin and solutions of bilirubin in serum were carried out, and it was shown that the proportion between the extinction of the diazo reaction with filter S 61 and that of the spectral absorption of bilirubin with S 43 in the Pulfrich photometer (E 61/E 43) for solutions in serum had a constant value with only little variation from one serum to the other.

The determination of the proportion E 61/E 43 of different sera showed values considerably below the characteristic value for pure bilirubin serum solution for most of them. Consequently the occurrence in human serum of yellow substances different from bilirubin is to be looked upon (by the author) as an established fact. It was also demonstrated that the concentration of these yellow substances in serum was of the same magnitude as the bilirubin concentration. It exceeded the concentration of the serum carotenoids considerably. Further it could be demonstrated that hemoglobin or biliverdin could not be the cause of these findings.

The chemical nature of the nonbilirubin yellow substance and its physiological properties are discussed and the hypothesis is advanced that in human serum it is identical with the xanthorubin of the patetomized dogs and with the pyrrol compounds bilifuscin or mesobilifuscin. DAVID H. LYNN, M.D.

Clagett O. T., and Hawkins, W. J.: Cystic Disease of the Liver. *Ann. Surg.* 1946 123 111

Simple solitary cysts of the liver are localized and usually circumscribed, and occasionally they possess a pedicle. The result is that surgical treatment is far more often possible for solitary cysts than for cystic disease, wherein the lesion is more generalized with reference to the liver.

The authors' patient was a married man 39 years of age. His chief complaints were a feeling of full

Fig. 1. Left lobe of the liver involved by cystic disease; tourniquet applied around its pedicle. Inset: Removal of left lobe of liver and closure of pedicle with interrupted mattress sutures. (Courtesy of J. B. Lippincott Co.)

ness and dull aching in the epigastrium. This distress had been present for 4 years. The symptoms progressed until at the time of his examination at the clinic, he was aware of a large mass in the epigastrium and was unable to ingest even a moderate amount of food without feeling discomfort. In spite of the normal results obtained in investigating the pancreatic function, it was thought that the epigastric tumor was probably a pancreatic cyst.

Accordingly on August 19, 1944, operation was performed through a primary upper left rectus incision. Immediately a portion of the mass containing multiple various sized cysts presented itself into the incision. On further examination it was found that this represented the left lobe of the liver. Examination of the right lobe showed it to be normal in appearance. Palpation of both kidneys was then done and neither seemed to be cystic. By separating numerous adhesions from the mass, a relatively narrow pedicle was encountered adjacent to the ligamentum teres. A Bethune pneumocystomy tourniquet was then applied around the pedicle (Fig. 1) and the entire left lobe of the liver was removed en masse. The remaining stump was closed with interrupted chromic catgut sutures. The tourniquet was then removed and there remained only minor oozing of blood from the stump.

Five grams of sulfanilamide powder were sprinkled into the area and one double iodoform pack was placed to control what oozing might occur from the stump. Two Penrose drains were brought out through the incision. The specimen included the entire left lobe of the liver, consisting of multiple cysts lined by epithelium of the bile duct type. The postoperative convalescence was uneventful.

As far as the authors were able to determine from the literature, this case is the first one reported in

which the entire left lobe of the liver was removed for cystic disease. The only other reported case of a similar nature was that of von Haberer who in 1908 removed the entire left lobe of the liver because of a nonparasitic solitary cyst which occupied the greater part of that lobe.

Most authors agree that the cause of the simple solitary cyst is some form of local obstruction in the biliary tract with a resultant retention type of cyst. In cystic disease however opinion seems to be divided since there are various hypotheses as to its pathogenesis.

All of the articles reviewed make special mention of the fact that cystic disease of the liver is usually associated with cystic disease elsewhere—notably in the kidney. When there are associated renal lesions, they are usually far more advanced than the lesions in the liver.

If a cystic liver has enlarged to the point of causing a palpable mass, the identity of which cannot be proved then exploration of the abdomen is advisable. When such a lesion is encountered two alternatives are possible (1) the involved portion can be removed or (2) nothing should be done. The decision to excise the lesion must be made only after several factors have been considered. The kidneys should be palpated. If they too are involved seriously then there is no point in attempting to excise a portion of the liver; the hazards of this procedure are well recognized.

If the patient has been asymptomatic in spite of the presence of the cystic liver and if removal of the tumor would involve too great a risk, then one would be justified in doing nothing. If on the other hand, the tumor is interfering with the patient's well being, the kidneys are without palpable involvement, and removal of the lesion would not be too hazardous a procedure, then extirpation certainly is justifiable.

Milrizz, P. L.: The Diagnosis of Choledocholithiasis (Diagnóstico de la colédocolitiasis). *Pravda méd. argent.* 1945, 3 9039.

The value of the usual preoperative clinical and laboratory procedures for the detection of stone in the common duct and/or the adjacent hepatic bile passages is admitted, but the author deprecates the fact that they should play more than a modest role in the integral diagnosis of choledocholithiasis. Attempts at preoperative filling of the common bile duct with shadow producing medium by reflux from the duodenum (duodenal catheterization) is mentioned without enthusiasm and as being only rarely successful. Even the nonsurgical cholangiography of Lee of Philadelphia, whereby the gall bladder is injected with a shadow medium through a peritoneoscopy is regarded askance as being essentially a surgical procedure, as being applicable to not more than 50 per cent of the gall bladders, and as being of uncertain innocuity because it leads to biliary peritonitis and other accidents. In fact, all of these procedures pale in significance in face of the inescap-

able duty of the surgeon, not only to arrive at the diagnosis of choledocholithiasis, but also to be certain that the patient has been freed of all the stones in the bile duct. Even laparotomy with direct palpation of the choledochus, choledochotomy with instrumental probing of the bile passages and perhaps the choledochoscopy of McIver are not without objections, and although of aid in determining the presence of canalicular lithiasis in a large proportion of cases, they do not afford an absolute diagnosis.

Operative cholangiography on the other hand has contributed extensively in confirming the diagnosis of stone in the bile tracts. It is a valuable source of information in lithiasis of the ampulla of Vater and intrahepatic stone. It furnishes capital data on the pseudotumoral form of choledocholithiasis, and represents an irreplaceable recourse for providing assurance that all of the concretions have been removed from the principal bile duct. In the case of the calculus located at the ampulla of Vater even when it is too small to show on the film as the usual punch press defect at the lower end of the common bile duct (where the usual outline of the ampulla would be expected) or as the less common defects such as the right angled uniform parrot beaked, festooned and angulated defect appearance, its presence will at times be suspected by the reflux into the duct of Wirsung—which is more persistent than in the cases of simple dystonia of the sphincter of Oddi.

This question of persistence, however, also brings up the matter of the functional criterion in the roentgenological examination of these patients, that is, the taking of one or more cholangiographic exposures following the original one. For instance, in 1 patient of the author's material, the first film disclosed a typical inflammation of the sphincter of Oddi with the usual "Havana cigar" tip to the ampulla; another film was taken and this proffered the classical image of calculus of the papilla (punch press defect) with injection of the duct of Wirsung. In another the first exposure depicted a punch press defect, while the subsequent film showed the condition to be normal. Of course, the taking of two, or of several films at varying intervals is not of itself sufficient to solve all the problems in stone in the bile ducts; frequently all attainable facts will have to be marshaled to arrive at a correct diagnosis.

In 1 patient a history of persistent icterus caused the author to explore the nonfilling left hepatic duct where, in spite of the fact that hepatic duct stones are nearly always multiple, and primary stone in the hepatic duct without accompanying involvement of the common duct is a great curiosity, a single large stone, the shape of a Winchester bullet with nose pointing downward was extracted from the hepatic duct. After this the hepatic system filled normally with shadow medium. At operation in this case the choledochus was found to fill and empty into the duodenum in an unobstructed manner.

However stone is not the only condition preventing the filling of part of the bile tract during the

operative cholangiographic examination. It may be necessary in addition to injecting the shadow mixture through the gall bladder or the stump of the cystic duct, to open the choledochus itself and make an injection through the choledochotomy opening. Or it may even be necessary to provide the injecting syringe with a filiform catheter and push this into the different sections of the bile tract system. This is likely to be necessary in the dilated and distorted passages of the longstanding recurring case of gallstones.

Even if all methods have been exhausted without an explanation of a longstanding clinical history of mechanical icterus, one is still justified in suspecting an obstruction below any of those uncovered: a concretions in the ampulla of Vater, a stenosing pancreatitis or inflammation of the sphincter of Oddi. In any case the ampullar stone is the more probable, and one is justified in resorting to a transduodenal papillotomy.

One of the most difficult problems is the differentiation between the obstruction due to stone accompanied by a pseudotumor that is the matting together by adhesions of the epiploon, colon, gastric antrum and pylorus, pancreas and bile sac, and a true neoplasm. Here again however the author holds that operative cholangiography will be of assistance, in that in the obstruction by stone the injected shadow material surrounds the concretion and reveals the lacunar characteristics of this form of obstructing body, while in the neoplastic type of block the hindrance to the flow of iodine-acetate will be complete.

JOHN W. BRENNAN, M.D.

Robertson H. E.: Silent Gallstones. *Gastroenterol.* 67: 1945 5 345

The author gives a very comprehensive historical review of the literature concerning gall stones. He surveyed the results of postmortem studies of the gall bladder made at the Mayo Clinic during the 10 years from 1934 to 1943 on persons over 20 years of age. A total of 1,027 had gall stones: 497 males and 530 females. In this study no attempt was made to determine the percentage of patients who at postmortem did not have, and apparently never had gall stones. The author with a coauthor found that of 16,036 postmortem examinations at the same clinic in the years from 1910 to 1942, 16.3 per cent (12.6 per cent in males and 22.6 per cent in females) revealed that the person had or had had gall stones. In the present review the histories of these patients were carefully reviewed and it was found that in 626 (61%) there apparently had been no suspicion by the patients or their attending physicians that gall stones had been present. The remaining 400 cases could be fitted into various and sometimes overlapping categories: for example, 305 of the patients had undergone one or more operations for gall stones while in 80 cases stones were discovered accidentally at laparotomy for some other condition.

The assertion by some physicians that a certain percentage of silent gall stones in any given series

is a reflection on the diagnostic abilities of the attending physicians is unwarranted. After gall stones have been accidentally discovered the attribution of the symptoms and signs to their presence is not always on a sound clinical or pathological basis. About 50 per cent of gall stone cases remain unrecognized. Not all gall stones discovered during life warrant operation for their removal; they are an individual problem in each instance and are usually accorded that importance which the best welfare of the patient warrants.

EARL O. LATIMER, M.D.

Skelton, M. O. and Tovey G. H.: Congenital Obliteration of the Bile Ducts and Icterus Gravis Neonatorum. *Brit. M. J.*, 1945 2 914

The authors state that icterus gravis neonatorum and congenital obliteration of the bile ducts may both be associated with biliary obstruction. In the former condition the canaliculi may be plugged by bile thrombi probably as the result of damage of the hepatic cells. Once these thrombi have formed they may aggregate to produce an obstructing mass in the extrahepatic bile ducts, the final effect being to add an obstructive element to the jaundice caused by the hemolysis. Occasionally the biliary epithelial cells become swollen and this tends to aggravate the condition. Desquamated epithelial debris lying free in the lumen of the bile ducts may add further to the obstruction. In some cases of icterus gravis of long standing biliary stasis may occur and produce a picture of hepatic cirrhosis which is very similar to that of congenital obliteration.

Two cases of icterus gravis are described, in which obstruction was believed to have been due to blocking of the large bile ducts with inspissated bile. In one case the plug was dislodged at operation. The fathers of both patients as well as the patients themselves were rhesus positive. The mothers were rhesus negative with Rh antibodies in their blood.

The authors describe 2 other cases of congenital fibrosis of the bile ducts, in both of which there was a rhesus incompatibility demonstrated in the parents. Two siblings of one of these parents bore subsequently died of jaundice. The findings at autopsy included erythroblastosis and kernicterus in both cases.

It is not suggested that all cases of congenital obstruction of the bile ducts are associated with erythroblastosis fetalis, but the fact that some of them appear to be associated with icterus gravis neonatorum is of practical importance. Consequently any family showing a history of congenital obliteration should be examined for evidence of rhesus incompatibility. Only in this way can preparations be made to anticipate hemolytic disease which may occur in subsequent children.

As a prophylactic measure in patients with icterus gravis, the practice of massage over the region of the gall bladder is recommended in the hope of avoiding plugging of the bile ducts and hence obstructive jaundice.

THEODORE B. MARSHALL, M.D.

Smith H. G., Pratt Thomas, H. R., and Mace, L. M.: Re-Establishment of Pancreatic Secretion Into the Intestine after Division of the Pancreas; An Experimental Study. *Arch Surg* 1945 51: 164.

As a result of progress in the radical operative treatment of carcinoma involving the head of the pancreas and the peripancreatic region, pancreatic cancer can be approached today with a clearer concept of the operative technique and with a reasonable chance of accomplishing a surgical cure.

Despite widening experience with this difficult surgical problem, the incidence of postoperative complications remains high. Some of the more distressing postoperative sequelae are referable to the stump of the divided pancreas and consist of external pancreatic fistula, acute pancreatic necrosis, retention cyst, and chemical or "enzymatic" peritonitis. The pancreatic stump has been handled generally speaking by one of two methods: occlusion by inversion of the sutures with or without ligation of the duct of Wirsung; and some form of pancreaticoenterostomy in which the stump is implanted into a segment of intestine. As regards the first method, digestion of the inverting sutures occurs all too frequently with resulting leakage of the pancreatic juice and the consequent development of one or more of the complications mentioned. As to the second method, the question has been raised whether reimplantation of the pancreatic duct into the gastrointestinal tract is necessary inasmuch as it is well established that many patients live normal, healthy lives after being deprived of the external secretions of the pancreas. On the other hand, many such patients suffer severely from disturbances of fat digestion in the form of steatorrhea and malnutrition so that it is important, whenever possible to maintain the external secretory function of the pancreas. An evaluation of techniques of pancreaticoenterostomy employed by various investigators directs attention to two important factors: all procedures (with the exception of Cattell's simple method) involve an open anastomosis, with a consequent breach in asepsis and most of them are too time consuming. This experimental study was conducted in order to develop an aseptic technique which can be performed with minimal loss of time and preservation of the external pancreatic secretions.

Experiments were done on 33 dogs. In 15 animals the pancreas was divided at the junction of the uncinate process and the body without disturbing the relationships of the latter to the duodenum and thereby leaving the junction of the main pancreatic duct intact. The exposed transected surface of the pancreatic body was closed with sutures after ligation of the duct. In this manner the uncinate process was isolated entirely from the remainder of the gland, and its independent blood supply was maintained. The divided end of the duct in the uncinate process was allowed to retract into the parenchyma of the gland without its being ligated. The stump of the divided uncinate process was then implanted

into the jejunal wall in an incision that extended down to, but not through, the jejunal mucosa, and was made secure in the jejunal wall by fine sutures. The remaining 7 animals were operated on by a modification of the technique of Cattell. The procedure was similar in detail to that described, except that the uncinate duct was dissected free so as to protrude from the divided stump of the gland. A crushing ligature of fine surgical gut was tied about the protruding duct and one end of the ligature was passed as a suture through the exposed jejunal submucosa and tied firmly to the other end which brought the duct against the mucosa in a firm necrotizing ligature. The pancreatic stump was secured into the jejunal wall in the usual manner. All animals survived and remained in good condition. Observations of the state of the pancreaticoenterostomy were made at intervals varying from 7 to 48 days by the following technique.

The abdomen of each dog was reopened under anesthesia and the jejunum adjacent to the pancreatic attachment was opened widely which exposed to inspection the jejunal mucosa at the site of the pancreatic implantation. A concentrated, highly active preparation of secretin was then injected into the vena cava. If a fistula had developed from the uncinate stump into the jejunum, pancreatic juice could be seen grossly dripping from the fistular orifice in the mucosa. If fistula formation had not occurred, no response to the secretin was noted. The potency of the secretin was tested by opening the duodenum and observing simultaneously the flow of bile and pancreatic juice from the ampulla of Vater. Of the 33 animals studied, 15 showed definite secretion of pancreatic juice at the pancreaticojejunal junction after the intravenous injection of secretin.

After the functional status of the pancreaticojejunal junction had been determined, the entire uncinate process and the attached jejunum were excised for microscopic study with particular reference to acute pancreatitis, pancreatic fibrosis, and the development of pancreaticojejunal fistulae. None of the animals showed gross evidence of active peritonitis or fat necrosis. There was some evidence of acute pancreatitis in 37 per cent of the animals but pronounced diffuse pancreatitis was found in only 3 animals. Each of these animals appeared to be quite healthy. Some degree of scar tissue formation was demonstrable in 91 per cent of the animals but fibrosis was considered pronounced in only 1 animal. This animal presented an indurated and atrophic stump but no microscopic evidence of fistula. Despite these findings, the response to secretin was positive although the flow of pancreatic juice was sluggish. Definite microscopic evidence of a junction between the mucosa of the uncinate duct and the mucosa of the jejunum was detectable in 59 per cent of the animals. It is pointed out that a fistula may exist despite failure to demonstrate it microscopically by the secretin test and also by the injection of water through the

uncinate duct into the jejunum. No external pancreatic fistula was encountered and only 1 retention cyst which complicated the procedure was found.

JOHN L. LUNDQVIST, M.D.

Varco, R. L.: A Method of Implanting the Pancreatic Duct into the Jejunum in the Whipple Operation for Carcinoma of the Pancreas. *Surgery* 1945 18: 569.

The author presents a technique for anastomosing the pancreatic duct to the bowel in cases of resection

of the head of the pancreas. This procedure has now been successfully carried out in 4 patients.

The pancreatic duct is isolated with a short extra glandular section preserved when the gland is transected. Two fine silk sutures are placed in the wall of the duct to hold it open. A two-holed catheter somewhat larger than the duct is selected—about a size 12. Eight centimeters of the catheter are stretched over a Keith skin needle which serves as an obturator and impaled at a point on the catheter wall slightly eccentric to the tip. As the segment of

Fig. 1. The two drawings at the top indicate approximations of the results in 1 and 2 by malignancy and diagram the visceral configuration in 3. The anastomosis is shown in 4. The diagram of the operative procedure is shown in 5. The technique of implanting the pancreatic duct into the jejunum is shown in sketches A to F.

catheter is stretched over the obturator its transverse diameter is decreased. It is held stretched by clamping the tube and obturator firmly with a hemostat. An oblique section is now cut from the tube, care being taken to place this distal to the tented wall of the catheter. The stretched catheter is slipped a short distance into the pancreatic duct and on release of the hemostat the catheter is permitted to resume its normal diameter and it is snugly held in the duct. A fine ligature may if desired be used to hold the extraglandular duct against the catheter, but usually this is unnecessary.

With fine sutures the posterior capsule of the pancreas is sutured to the jejunum at the site selected for anastomosis. A fine puncture hole is made with a Keith needle through all layers of the bowel wall and the catheter is forced through this small puncture wound into the lumen of the bowel, which gives a very close fit. Two fine sutures are placed between the connective tissue adjacent to the duct and the serosa next to the puncture site. The remainder of the capsule of the pancreas is sutured to the bowel serosa, namely the anterior aspect.

In 4 cases in which this method has been used there has been no pancreatic fistula.

EARL O. LAMMIE, M.D.

Wakim, K. G., and Mason, J. W.: The Effects of Adrenalin and Nembutal Anesthesia on Blood Constituents Before and After Splenectomy. *J Lab Clin M* 1946, 31, 8.

The authors studied the effect of adrenaline and of nembutal anesthesia on the concentration of hemoglobin and plasma proteins and on the red and white blood cell counts in intact and splenectomized dogs. The lateral surface area of the spleen was determined under nembutal anesthesia before and after the administration of adrenaline.

They found that the intravenous administration of adrenaline increases the concentration of hemoglobin and the red cell count in the circulating blood to a much greater extent in intact than in splenectomized dogs. Nembutal anesthesia causes hemodilution with a reduction in the hemoglobin concentration and in the red cell count, and a slight reduction in the plasma protein concentration. The size of the spleen in dogs under nembutal anesthesia was decreased about 66 per cent by the intravenous administration of adrenaline. The blood squeezed out by the spleen during its contraction under the influence of adrenaline had an average hemoglobin concentration about 11 per cent higher than that of jugular blood.

Bradford, B., Jr., Battle, L. H., Jr. and Pasachoff, S. S.: Abdominal Surgery in an Evacuation Hospital. *A. S. Surg* 1946, 3, 32.

The observations presented were made on 341 abdominal war wounds operated upon in a single evacuation hospital from the middle of June, 1944

through December 1944 in the European theatre. The distance of the hospital from active fighting varied from 4 to 30 miles. The cases include all of those with penetrating and perforating wounds involving the peritoneum perforating wounds of the rectum and major retroperitoneal injuries requiring celiotomy.

The diagnosis of intra-abdominal perforation was usually obvious in battle casualties. Signs of peritoneal irritation were frequently absent during shock, but appeared when it was relieved. Symptoms of peritoneal irritation appeared late in wounds of the left colon, and a silent abdomen was the rule when peritoneal irritation was present. Shoulder pain was not important, and the absence of liver dullness was not a constant finding. Proctoscopy and sigmoidoscopy were invaluable in uncovering rectal and sigmoid perforations. Location of the foreign body roentgenologically was helpful. Urinary alysis was a routine procedure in all cases of abdominal injury and with catheterization was useful in exposing wounds of the urinary tract. When in doubt as to whether intraabdominal perforation existed, an exploratory laparotomy was done.

Preoperative management is stressed as being frequently the decisive factor in the outcome of cases of abdominal injury. All patients were sent to the shock ward first, whether shock existed or not. Both blood and plasma were used but the former was believed to be of most value and a quantity of 1 liter or more was usually necessary to relieve shock in individual cases. Patients with active intra-abdominal bleeding and abdominal eversion were sent directly to surgery with blood running because they did not respond to shock therapy until surgery was done. In judging the optimum time for surgery the patient's general condition and skin warmth were valuable aids. Single blood pressure readings were misleading but multiple readings were helpful. However patients with a blood pressure of below 80 systolic did not tolerate surgery well. The time interval before surgery was not found to be important except in cases of continued bleeding and eversion at intervals and some patients under shock therapy were operated upon as late as 36 hours after injury however the policy was to give all patients the benefit of surgery whether or not they responded to shock therapy.

The mortality in the cases of patients who were operated upon 6 hours from the time of injury was 30 per cent. The mortality dropped in the subsequent six hour periods until at the 24 to 30 hour period it was but 10 per cent. The high early mortality was partly explained by the fact that the most desperate cases were operated upon first.

Where multiple major wounds existed the policy was to perform the separate procedures over a period of days rather than have several operative teams working at the same time.

In most cases the anesthetic of choice was nitrous oxide-oxygen, and ether in a closed system prefer

Bradford, B., Jr., Battie, L. H., Jr. and Pasachoff, S. S.: Abdominal Surgery in an Evacuation Hospital. *Ann Surg* 1946 3: 3.

The observations presented were made on 341 abdominal war wounds operated upon in a single evacuation hospital from the middle of June 1944

through December 1944 in the European theatre. The distance of the hospital from active fighting varied from 4 to 30 miles. The cases include all of those with penetrating and perforating wounds involving the peritoneum perforating wounds of the rectum and major retroperitoneal injuries requiring celiotomy.

The diagnosis of intra-abdominal perforation was usually obvious in battle casualties. Signs of peritoneal irritation were frequently absent during shock, but appeared when it was relieved. Symptoms of peritoneal irritation appeared late in wounds of the left colon, and a silent abdomen was the rule when peritoneal irritation was present. Shoulder pain was not important, and the absence of liver dullness was not a constant finding. Proctoscopy and sigmoidoscopy were invaluable in uncovering rectal and sigmoid perforations. Location of the foreign body roentgenologically was helpful. Urinalysis was a routine procedure in all cases of abdominal injury and, with catheterization, was useful in exposing wounds of the urinary tract. When in doubt as to whether intraabdominal perforation existed an exploratory laparotomy was done.

Preoperative management is stressed as being frequently the decisive factor in the outcome of cases of abdominal injury. All patients were sent to the shock ward first, whether shock existed or not. Both blood and plasma were used, but the former was believed to be of most value and a quantity of 1 liter or more was usually necessary to relieve shock in individual cases. Patients with active intra-abdominal bleeding and abdominal eversion were sent directly to surgery with blood running because they did not respond to shock therapy until surgery was done. In judging the optimum time for surgery the patient's general condition and skin warmth were valuable aids. Single blood pressure readings were misleading but multiple readings were helpful. However patients with a blood pressure of below 80 systolic did not tolerate surgery well. The time interval before surgery was not found to be important except in cases of continued bleeding and eversion at intervals, and some patients under shock therapy were operated upon as late as 36 hours after injury; however the policy was to give all patients the benefit of surgery whether or not they responded to shock therapy.

The mortality in the cases of patients who were operated upon 6 hours from the time of injury was 30 per cent. The mortality dropped in the subsequent six-hour periods until, at the 24 to 30 hour period, it was but 10 per cent. The high early mortality was partly explained by the fact that the most desperate cases were operated upon first.

Where multiple major wounds existed the policy was to perform the separate procedures over a period of days rather than have several operative teams working at the same time.

In most cases the anesthetic of choice was nitrous oxid oxygen, and ether in a closed system, prefer

ably with intratracheal intubation. Open drop ether was valuable for patients in severe shock from internal hemorrhage. Spinal anesthesia and pentothal were unsatisfactory.

In combined chest and abdominal wound the thoracic problem was handled first. The trans-thoracic approach to the diaphragm was most useful in treating wounds of the diaphragm, spleen and some gastric wounds. Paramedian incision with separation of either of the recti muscles were used most frequently. Exposure through subcostal incisions proved very useful especially in cases with injuries of the stomach, liver and spleen and the hepatic and splenic flexures of the colon.

The authors state that systematic examination of the abdominal contents is important. Suture of wounds of the small bowel is preferable to resection and end-to-end suture was the procedure of choice following resection. Enterostomy of the small bowel should not be done.

Small wounds of the cecum and ascending colon were sutured and a large Pezzar catheter was placed in the cecum as a safety valve. In the transverse descending and sigmoid colon the Mikulicz or preferably the loop-type of colostomy was performed. In rectosigmoid perforations those within the peritoneal cavity were sutured with a proximal

terminal sigmoidostomy to divert the fecal stream. In extraperitoneal perforations of the rectum adequate drainage with removal of the cecum if necessary and a proximal colostomy were done.

Wounds of the liver were managed by packing or the use of free or clef graft. Wounds of the spleen usually required peritonectomy.

Abdominal incisions were carefully closed in layers and reinforced with silk or wire retention sutures. Drainage of the peritoneal cavity was unnecessary except in cases of wounds of the liver.

Postoperative care included adequate hydration and the liberal use of plasma and whole blood to maintain blood protein levels. Wagon tree serum was used actively in all postoperative abdominal cases. Penicillin was given prophylactically in the immediate postoperative period. Vitamin C and thiamin were given orally. Penicillin was used routinely in all cases and is given partial credit for the low incidence (1.6 per cent) of pulmonary infection. Postoperative wound infection was rarely encountered and this was attributed to the use of penicillin and the sulfadiazine also postoperative intestinal obstruction in the early postoperative period even after extensive surgical procedures was rare.

JAMES K. H. 1971 MD

GYNECOLOGY

UTERUS

Elsen, D., and Goldstein, J.: Lipiodol Intravasation during Uterosalpingography with Pulmonary Complications. *Radiol* 57 1945 45 603

The accidental intravasation of lipiodol into the venous system of the uterus during uterosalpingography has been repeatedly described in the literature. As a rule there were no ill effects except perhaps slight temporary leucocytosis. In rare cases pulmonary and cerebral embolism and pulmonary infarction were noted.

In an attempt to study the mechanism of lipiodol embolism in the lungs Sicard and Forestier injected from 2 to 4 c.c. into the cubital vein. The lipiodol reached the lungs in 3 or 6 seconds remained there for from 6 to 8 minutes and then suddenly disappeared. The only effect in the patient was a slight cough. Walther injected lipiodol into the ear vein of rabbits. He found that practically all of the oil became arrested in the lungs where

it underwent two processes. The major part was broken up into iodine and fat, the iodine being excreted through the kidneys during the first 4 days as potassium iodide and the fat being saponified and carried away by the circulation. A smaller part of the lipiodol became phagocytosed. Walther also suggested that an inflammation may develop around fat droplets because of bacteria carried along by the lipiodol from the uterus.

A review of the literature revealed that the various authors attributed the intravasation to trauma of the endometrium during the injection, to excessive pressure and to an increased permeability of the receiving sinuses such as is observed in idiopathic uterine bleedings or immediately after menstruation.

The authors themselves noted intravasation of lipiodol during uterosalpingography in a woman 25 years of age. The case is briefly described and illustrated (Fig. 3). The afternoon after the injection the patient developed a dry cough with a temperature of 102 degrees. The next day her cough increased and she brought up bloody sputum. The temperature remained high until the fourth day when it dropped to normal. The cough persisted, however, and a roentgenogram of the chest on the sixth day revealed a dense patchy opacity involving the lower two-thirds of both lungs. Another roentgenogram 1 month later showed practically a normal appearance.

In conjunction with this case the authors recommended the following precautions: (1) uterosalpingography should not be performed sooner than from 8 to 10 days after the menstrual period or any operation on the uterus; (2) the position of the uterus should be determined preliminarily by the use of a sound and in case of angulation the injection should be done by properly circumventing the angulation so as to avoid trauma to the endometrium; (3) the pressure of the injection should not exceed from 140 to 200 mm. of mercury a manometer being used for control; and (4) the amount of lipiodol injected should be no more than is necessary to fill the uterus and tubes with a slight spill.

T. LECUTIA M.D.

Morris, P.: Hydrometrocolpos in Infancy—A Cause of Urinary Retention, Intestinal Obstruction and Edema of the Lower Extremities. *Am J M* 54 1945 75

A 7 weeks old girl who had been passing thin ribbonlike stools with difficulty for about 3 weeks, and for a day had only slightly wet two diapers, suddenly developed swelling of the feet and a purplish discoloration of the lower extremities. Also the previous day blood flecks had appeared in the stool and intussusception was suspected because of the presence of a mass in the lower abdomen. In

Fig. Lipiodol intravasation into uterine venous plexus and the ovarian vein. The latter resemble ureters, being filled their entirety on the right side the vena cava and on the left up to and including the renal vein.

addition to the large cystic mass extending upward from the pubis and apparently slightly more toward the right side reaching to 2 cm. above the umbilicus, there was a peculiar bulge at the vulva, cystic in appearance, pointing anteriorly and somewhat resembling a rectocele with the distended viscus pushing into it.

At laparotomy after the bladder had been emptied by catheterization a second mass appeared behind it. This was recognized as the distended uterus and vagina. Pressure on this mass, which was only about 5 cm. in diameter caused an increased tension in the vulvar hudge which was then incised externally. A considerable amount of a thin slightly milky fluid escaped and the mass collapsed, which allowed the rest of the urine to be emptied easily from the bladder. The fluid contained some white blood cells but the culture was sterile. The child died about a week later death apparently having nothing directly to do with the abnormal condition reported.

The author thinks that patients with hydrometocolpos should not ordinarily be subjected to laparotomy as simple incision of the vaginal membrane entirely relieves the condition. Preliminary aspiration by needle of some of the cyst fluid and injection into the cyst of 50 c.c. of diatriz followed by anteroposterior and lateral roentgen ray views (as suggested by Mahoney and Chamberlain *J. Pediat.*, 1940, 17, 772) will clearly establish the diagnosis of the condition.

The author wonders if many of these patients are not escaping detection as the condition becomes more or less quiescent about 2 weeks after birth when the glandular activity of the vagina and cervix regresses with exhaustion of the store of circulating estrogen left by the mother. With an imperforate condition of the hymen or residual embryonic vaginal septum as the case may be, the condition may develop again about the time of puberty and lead to the later development of the not infrequently observed hemistocolpos of the adolescent girl.

Calvo M. and Botella, J.: Hormonal Conditions in Uterine Myoma and the Genesis of the Menstrual Disturbances in Myomatous Women (Sobre las condiciones hormonales en el mioma de útero y la génesis de los trastornos menstruales de las miomatosis). *Rev. españ. obst.*, 1945, 3, 87.

This article is the third of a series of publications by these same authors in preceding numbers of this same journal, of which the first (Calvo y Botella *Rev. españ. obst.*, 1944, 1, 1) demonstrated the pre-dominance (four fifths of the patients with myoma) of incomplete cycles that is persistent follicles and anovular cycles. The second (*Ibid.*, 1944, 1, 165) showed that in almost three fourths of the myomatous women the secretory phase of the menstrual cycle did not develop. These findings corresponded closely to those in the first article. In addition the reader is referred to the thesis of one of the authors (Calvo Marcos *Tesis doctoral*, Madrid 1943) for a

detailed discussion of the techniques employed in this series of investigations.

In the two previous articles the investigations had led the authors to believe that there is actually an inundation of the blood of the myoma patient by estrogenic hormone viz. that the blood hormone is higher than normal, although the excess seems due rather to a constancy of secretion (anovular cycle) than to a high titer at any one phase. This constancy of secretion is designated by the authors as a rhythmic hyperestronism. It also seemed to them that the pathological bleeding so characteristic of the myoma has a functional origin that is it is bound up with the endometrial functional changes incident to normal menstruation.

In this report, on the other hand there are presented the shortcomings in the authors' findings, militating against unqualified acceptance of any such conclusions as those just cited.

The urine of 8 myomatous patients was tested for the elimination of estrogenic hormones on castrated adult white mice according to the method of Siebek and, although it is admitted that the urinary estrogenic elimination is not now regarded as a reliable criterion for indicating its level in the blood, it was found that the urinary elimination was neither constant nor excessive. In only 2 instances was the titer higher than normal and even in these cases the excessive elimination was not very marked and the tentative inference is offered that the endocrine disturbances of the myoma are due rather to the continuity of follicular secretion (anovular cycle) than to an actual increase in quantity at any particular time.

In studying their material the authors found that the incidence of the various patterns of menstrual manifestations in myoma showed in accord with practically all statisticians on this subject, a rather striking correlation of figures under all conditions. In their own material there was more than 50 per cent of patients complaining of menorrhagias more than 10 per cent with metrorrhagia, 3 per cent with eumenorrhagia and 4 per cent with amenorrhoea, and these proportions of characteristic manifestations were maintained except perhaps for a slight pre-dominance of copious menorrhagias in the frankly hyperplastic endometrial specimens no matter what endometrial phase was present.

The authors therefore, conclude from these studies that the bleeding in these myomatous patients is not due to a hormonal metropathy but rather to a vascular condition. In conformity with the older theories it is believed that it is due to the power of the myomatous new growth to induce congestion and changes in the capillary walls in the tissues overlying and contiguous to it. This perhaps is dependent upon its ability to produce some substance such as histamine or histaminoid substances and the effect is perhaps more or less sustained by the poor contractility and cavity deformation which is presented by the uterus itself.

ADNEXAL AND PERIUTERINE CONDITIONS

Jones, G. E. S., and Te Linde, R. W.: The Curability of Granulosa Cell Tumors. *Am J Obst* 945 50 691

Three cases of granulosa cell tumors have been reported in which recurrences developed not less than 14 years after the original operation.

All 3 patients died 18, 20 and 21 years respectively following the removal of the primary tumor in spite of the fact that the tumors were well encapsulated and showed no evidence of metastasis or implantation at the original operation. One tumor recurred in spite of bilateral salpingo-oophorectomy and hysterectomy.

One case, with widespread inoperable abdominal metastases, responded well to deep x ray therapy over a period of 3 years, but a subsequent recurrence of the growth proved refractory to treatment.

The total urinary estrogen values in 2 cases were not extremely high but stood within the range of values for normal cyclic women. However the values were well above those usually found in the authors' laboratory for postmenopausal women. All 3 of the patients fell into this age group at the time of the tumor recurrence. All 3 cases exhibited clinical signs of estrogenic activity at that time.

EDWARD L. CORNELL, M.D.

Usandizaga, M.: Tumors of the Round Ligament (Los tumores del ligamento redondo). *Rev chir* 1945 3 75

The author's patient was a woman of 39 years who had been married for 18 years and had gone through 3 pregnancies with normal childbirth in each instance. She entered the Provincial Maternity Hospital at Zaragoza with progressive enlargement of the abdomen since about 5 months previously and rather mild pains in the hypogastrium radiating into the lumbosacral region.

Examination revealed a hypogastric mass some what smaller than the head of an adult person of hard consistency very firmly fixed and with an irregular nodular surface. The impression of a small retroposed uterus was also obtained. The diagnosis was that of an intraligamentary solid tumor.

At operation a tumor mass was uncovered. It was somewhat smaller than an adult man's head with multiple lobulations and of firm consistency. It was situated almost entirely beneath the peritoneum. The mass appeared to be in direct continuity with the uterine end of the round ligament. On the right side the ligament passing intact from the uterus for about 3 cm. before being engulfed by the tumor mass. The broad ligament was well preserved, the tube and ovary of that side presenting a normal appearance. The peritoneum was freely movable on the surface of the tumor and the latter was easily enucleated. The uterine segment of the round ligament was sectioned and the coagulation carried to the region of the internal inguinal ring where a small vascular pedicle was likewise cut and tied. The tumor could

then be lifted out and the exact impression was given as though the round ligament had been excised between ligaments for its entire extent. This was followed by peritonization, closure of the abdomen, and an eventless postoperative course.

Histological examination of the tumor disclosed that its texture consisted of abundant trabeculae of smooth muscle cells in a framework of fibrous tissue.

An extensive bibliography is appended to this report of an extremely rare form of tumor.

EXTERNAL GENITALIA

Quinet, A.: Tuberculosis of the Vulva and Cervix—Contribution to the Medical Statistic of Brazil (Tuberculose da vulva e cervix—contribuição à casuística nacional). *A Brasil gin.*, 1945 10 1

The case of a negro woman of 34 years who had given birth to 7 full term children is here reported. It was one of the relatively rare instances of tuberculosis which attack the female sexual organs and one of the even rarer exemplars of the disease in which the attack was made on the cervix of the uterus. Finally it was one of the very rare cases in which the vulva was involved in the tuberculous ulcerative condition. In fact the author states that this is the first instance of vulvar involvement to be reported in the medical literature of Brazil.

The patient visited the out patient department (medical division) of the Hospital Moncorvo Filho in Rio de Janeiro a year and a months after the birth of her last child complaining of physical and mental exhaustion and weakness, loss of weight and pains in the region of the lower abdomen which became worse on exertion. Physical examination at this time disclosed some disseminated subcutaneous rales in the chest but no evidence of any involvement of the pelvic organs. A month later however the pains had become worse. The patient entered the hospital and was assigned to the medical section, where a small amount of ascites was determined and a hemorrhagic liquid showing no trace of the Koch bacillus was aspirated from the right pleural cavity. Paracentesis of the abdomen likewise yielded an ascitic fluid without trace of tubercle bacilli.

At the end of 2 months the effusions had cleared and the pains were gone. However the vaginal discharge was very marked and the patient was sent to the gynecological division. Here large irregular fixed masses were found on both sides of the cul-de-sac of Douglas and since one of these had begun to enlarge and soften the patient was transferred 15 days later to surgery where the intrapelvic process developed to the point where the uterus and other pelvic organs became enveloped in a single tumor mass.

At laparotomy some time later 2 liters of caseous, purulent material rather fetid and of a yellowish green color were aspirated from the mass in the pelvis and a biopsy specimen was taken from the

lining membrane of the pus pocket. On histological examination this specimen confirmed the suspected diagnosis of tuberculosis. No further surgical procedures appeared possible and the abdomen was closed.

It appears that it was during this later period that there developed from the anterior lip of the cervix the indolent appearing ulcerative process with sharply punched out edges and sluggish lardaceous floor which spread down the anterior wall of the vagina, and one patch about $\frac{3}{4}$ inch in diameter appeared on the internal aspect of the left labium major.

Biopsy specimens from the vulva, portio vaginalis, endometrium and endocervix disclosed (as depicted in excellent photomicrographs in the original article) the vascular characteristics lymphoid plasma, and Langhans cells as well as the scattered alcohol resistant bacilli of tuberculosis. The mycobacterium tuberculosis was cultured on Lowenstein medium and guinea pig inoculations proved positive.

JOHN W BRENNAN M.D.

MISCELLANEOUS

Dujovich, A.: Elytrocele (Eltrocele) *A. brasil gin.* 1945, 10: 116.

The elytrocele also variously known as vaginal hernia, enterocele vaginalis posterior Douglascele, prolapse of Forrie's hernia of the floor of the sac of Douglas, and colpocele posterior is rare but nevertheless more frequent than the anterior form of vaginal hernia. It is particularly important not to confound this condition with rectocele since a simple repair of the latter when accompanied by elytrocele, will usually result in recurrence. However other forms of defect of the pelvic floor usually accompany the elytrocele. It is well to be prepared to repair these at the same time.

The case history presented by the author was that of a woman of 55 years who had given birth to 3 children. Twenty nine years ago 4 years after the first accouchement she had noted a protrusion of the vulva, which was painful on physical exertion. The

condition became gradually more pronounced until 19 years ago when she underwent a pelvic repair—probably an anterior colporrhaphy and a colpoperineorrhaphy—with relief for 4 years. Then the protrusion and other symptoms returned. A pessary was worn for 7 years without relief and during the past 3 years the patient suffered from a sensation of heaviness in the vagina and on exertion a globular mass protruded from the vulva. The diagnosis at this time was genital prolapse colpocele, anterior cystocele, hypertrophic elongation of the uterine cervix colpocele rectocele and vaginal hernia of the pouch of Douglas (enterocele).

At operation which was entirely vaginal, the anterior wall of the vagina, together with the cystocele was first repaired and the elongated cervix amputated. The incision was then carried around back of the cervical stump and the posterior surface of the latter was followed closely to guard against injury to the hernial sac. The sac, however was easily identified and freed up to its neck. When the sac was opened, it was found to be lined with the peritoneum of the pouch of Douglas and to contain a loop of the sigmoid colon. The sigmoid was pushed back through the neck 3 fingers in width which was then closed by a purse string suture with No. 1 catgut and the sac itself was cut away. The closure was in turn reinforced by additional sutures including the posterior surface of the cervix and the rectovaginal fascia on each side, which had been previously dissected loose from the posterior vaginal mucosa. The vaginal mucosa was then sutured with interrupted sutures of No. 2 catgut to the posterior surface of the stump of the cervix, and the entire operation finished up with repair of the residual rectocele including the usual myorrhaphy of the levator muscles.

It is now a month since the patient was operated upon although there is some shortening of the vagina she seems to be definitely cured. Indeed, the prognosis is generally good in these patients, provided that the condition be correctly recognized.

JOHN W BRENNAN M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Dieckmann, W. J., Turner D. F. and Ruby H. A.: Diet Regulation and Controlled Weight in Pregnancy. *Am. J. Obst.*, 1945 50 701

The pregnant patient must have a proper diet, but this does not mean that she should have an unlimited caloric intake and, as a result, gain excessively in weight. The pregnant patient does not have to eat for 2 of her own size. The diet must be increased during the last trimester.

The necessary weight gain due to the physiological changes of pregnancy—fetus, placenta, amniotic fluid, uterus, blood volume, breasts—amounts to 6.7 kgm. Chesley calculates from reports in the literature a gain of 6.2 kgm. for the same physiological changes in pregnancy. There is no need for a total weight gain greater than 8 kgm. above the ideal weight. The first 3 months of pregnancy are characterized by either a little gain or a loss of weight. The average weight gain for the remainder should then be a maximum of 225 gm. (½ pound) per week.

Every patient whose total weight gain is over 10.9 kgm. does not necessarily have toxemia. Statistics show, however, that the incidence of toxemia is increased in the patients who gain more than 13 kgm.

If the patient's weight is ideal before pregnancy the maximum gain should be between 7 and 8 kgm. A diet containing 1,800 calories is required.

EDWARD L. CORRELL, M.D.

Lagercrantz, C. Electrophoretic Analysis of Serum in Pregnancy and in Pregnancy Toxemia. *Uppsala läk. fören. förh.*, 1945 5 17

An analysis of serum proteins in pregnancy and in pregnancy toxemia has been carried out previously by gravimetric, nephelometric, refractometric, or precipitation methods. These methods have shown quite consistently that during pregnancy both the concentration of serum proteins and the albumin-globulin ratio are lowered. These findings are more pronounced in toxemia, especially in cases in which there is much edema. Previous investigators assuming that the well recognized increased plasma volume of pregnancy is due largely to a plasma hydropnea have suggested that the decreased protein content is in the main a dilution effect. Because this decrease in total protein is due solely to a lowered albumin, they have regarded the unchanged value of the globulin as an expression of an absolute increase of this protein in the plasma. In pregnancy toxemia where still lower albumin values are found it has been suggested that these values are the result not only of further dilution but also of real loss of albumin. In the present study serum proteins were analyzed by

electrophoresis. The technique is carefully described.

Electrophoretic analysis was performed on serum from 16 normal nonpregnant women, 9 normal pregnant women in the second to seventh months of gestation, 15 normal pregnant women in the last month of gestation, and 19 pregnant women in the last month of gestation with varying degrees of toxemia. The analysis showed that:

1. The alpha and beta globulins increase both relatively and absolutely during normal pregnancy.

2. The albumin and total protein decrease during normal pregnancy.

3. Women with toxemia have a both relatively and absolutely larger alpha globulin than normal pregnant patients.

4. There is no significant difference in the electrophoretic patterns of umbilical cord serum after a normal pregnancy and after a toxemic one. Umbilical cord serum shows small amounts of alpha and beta globulins.

The author correlates these results with previous work, although he makes no attempt to draw any significant conclusions.

The alpha and beta globulins consist partly of lipids. It is known of course that in pregnancy the serum lipids are elevated. The increase in these globulin fractions may be related to the lipemia. In view of the small amounts of alpha and beta globulin found in the umbilical cord it is unlikely that the increase is caused by a transfer from the fetus.

The molecular weight of both alpha and beta globulin is much higher than that of either albumin or gamma globulin. Consequently in toxemia, when the permeability of the capillary walls may be pathologically increased, albumin and gamma globulin should leak through first and lead to a relative increase of alpha and beta globulin. The absolute increase, however, must be explained by some other factor than filtration alone.

L. JAMES TALBOT, M.D.

Gimeno, A. M., and Orengo, F.: Capillaroscopy in the Toxemias of Pregnancy with Special References to Differential Diagnosis (La capillaroscopia en las toxemias de embarazo, con especial referencia al diagnóstico diferencial). *Rev. esp. obst.*, 1945 5 2.

This is the conclusion of an article begun in the July issue of this same journal in which details of the technique and the criteria established by the authors in judging the results of their observations will be found.

The authors examined capillaroscopically 100 cases of toxemia, including 3 of chronic nephritis, 3 of vasculorectal disease, 22 of essential hypertension, 47 of mild pre-eclampsia, 17 of severe pre-eclampsia.

and 5 of eclampsia. These capillaroscopic examinations were made in the course of a broader investigation employing numerous other tests and methods of study such as blood pressure studies and studies of edema, of the effects of the administration of pituitrin and of congelation of the hematocrit findings of albuminuria and of sedimentation, and the results were correlated. When possible the observations were made both before and after delivery.

Capillary architecture does not show sufficient modification to permit of differentiation between the mild and the severe pre-eclampsia. Acute nephritis is distinguished by marked anomalies of form such as undulation serpentine formation intercrossing, anastomosis, visibility of the subpapillar plexus of the blood vessels. There are no characteristic alterations in the picture of essential hypertension. In chronic nephritis and in vasculorectal disease deviations of form are, in the first instance scarce (undulation, some serpentine deformities and at times visibility of the subpapillar plexus). In the second condition there are even fewer abnormalities consisting solely of a certain amount of diminution in the number of capillaries per field each vessel being somewhat narrower on the whole.

In general it is possible to demonstrate a relationship between the clinical picture and the capillary findings, however incongruities are frequently present. The blood current in acute nephritis can show findings as poor as those in eclampsia, and by the same token, much worse than those in chronic nephritis. In cases of essential hypertension and in vasculorectal disease there is a persistent constriction of the vascular bed with changing blood current velocities and at times an accelerated or even violent circulation.

The postpartum capillaroscopic examinations result in two classifications: the genuine toxemias (pre-eclampsia and eclampsia) and a group comprising all the other processes cited (chronic). In the first group the authors observe a total recuperation or at least a tendency toward recovery; in the second an established condition with slight modifications persists. The value of a careful postpartum revision for substantiating the diagnosis is seen.

The authors consider capillaroscopy a diagnostic method, which aids in the differentiation between genuine toxemias and vascular disease or a chronic kidney condition especially when employed in the postpartum period. It also possesses a limited but evident value in prognosis and may serve as a guide in bringing out the effectiveness of therapeutic methods the authors having frequently observed the improvement with diet with magnesium sulfate and especially with hypertonic glucose solution.

JOHN W. BRENNAN, M.D.

Davis, L. J., and Forbes, W.: *Thiouracil in Pregnancy; Its Effect on the Fetal Thyroid*. *Lancet*, Lond. 1945 249-250.

A case of mild thyrotoxicosis in a woman who was treated with thiouracil prior to and during preg-

nancy is presented. She died in the sixth month of pregnancy. The cause of death was uncertain despite autopsy examination.

The thyroid gland of the fetus was enlarged and hyperactive, as compared with a presumably normal gland from a premature infant, and showed histological evidence of considerable functional activity. It resembled the gland of an adult receiving too much thiouracil. It is suggested that thiouracil acts on the fetal thyroid after passing through the placenta. The administration of thiouracil to pregnant women and probably to nursing mothers demands caution.

GEORGE BLINCK, M.D.

Beerman, H. and Ingraham, N. R. Jr.: *Recent Advances in the Management of the Syphilitic Pregnant Woman*. *Med. Clin. N. America*, 1945 39-1463.

There is now general agreement that syphilis is exclusively transmitted to the fetus by the mother. Most evidence shows that the fetus is infected in the later months of pregnancy and not shortly after conception.

Routine blood testing in prenatal patients becomes a matter of great importance because 90 per cent of the women are unaware of their infections. In the experience of the authors there is no evidence that pregnancy impairs the sensitivity or specificity of the tests.

In the treatment, drugs with a strong spirillicidal action must be used. These are neosarsphenamine, arsenoxide and penicillin. Bismuth and mercury alone are not effectual. An outline for the use of these drugs is given, with the greatest discussion being devoted to penicillin. Treatment began at the fourth month of pregnancy and continued at weekly intervals to total not less than 4 gm. of neosarsphenamine, or the equivalent of arsenoxide with or without bismuth subsalicylate. Pregnant women tolerate arsenical and heavy metal treatment well but a urine examination and blood pressure determination before each treatment is important.

Penicillin therapy is the same as for the nonpregnant adult. The spirochaeta pallida was seldom found in the open lesions longer than 12 hours, and the lesion itself was completely healed in 1 week. The therapeutic shock at the beginning of treatment may be harmful to the fetus. A large percentage of the women develop abdominal pain, gastrointestinal disturbances and on several occasions presented symptoms of threatened abortion. For this reason the initial dose is reduced for the first 48 hours. A total dosage of either 1,300,000 or 2,400,000 Oxford units of sodium penicillin is satisfactory both to prevent infection of the fetus and to cure the disease in the mother. This total dosage is given intramuscularly 30,000 units every 3 hours with a reduction during the first 8 hours. The total treatment course takes 8 or 9 days.

Twenty-seven of the women treated at the University of Pennsylvania Hospital (Philadelphia) have thus far been delivered and their babies followed up

for periods which vary from 3 months to a year with no evidence of syphilis.

CATHERINE B. HART, M.D.

LABOR AND ITS COMPLICATIONS

Reanick, L. Spinal Analgesia in Operative Obstetrics. *Brit. M. J.* 1945 3 72

Although the safety of spinal anesthesia for general surgery has been generally accepted, its use in obstetrics is still considered dangerous. The author reports a series of 137 cesarean sections and 256 operative vaginal deliveries done under heavy narcosis (1 in 200 in 6% glucose in 3 c.c. ampules) spinal anesthesia.

Premedication was given to all women who were to be delivered by cesarean sections. It consisted of omopon gr 1/3 and scopolamine gr 1/300, given about 45 minutes before operation, and in addition, atropine gr 1/100 and ephedrine gr 1 for vaginal deliveries most of them had had some premedication during the labor but were given ephedrine gr 1.

The dosage for cesarean sections varied from 1.5 to 1.5 c.c. of the solution and for vaginal deliveries from 0.5 to 0.8 c.c., which gave anesthesia to just below the umbilicus.

The indications for and the types of cesarean section performed are summarized. 75 per cent of the sections were of the lower segment type. Of the 256 vaginal deliveries 136 were made by means of the outlet forceps, 108 by midforceps, 8 by high forceps, 6 by breech extraction, and 4 by craniotomy. Rotation of the head was performed 167 times.

No maternal deaths occurred in the cesarean group, while 2 of the patients delivered from below died (one because of pulmonary embolus and the other following sulfonamide therapy for pyelitis). In neither case was the anesthesia responsible for the death. Seven (5%) of the cesarean babies and 34 (13%) of those delivered from below died but none of these deaths could be attributed to the anesthesia.

The author considers the following to be the advantages of spinal anesthesia:

For the mother

1. It is safe when inhalation anesthesia is contra indicated.
2. It is safe in pre-eclampsia and eclampsia.
3. It is safe in essential hypertension.
4. Uterine atony and hemorrhage are rare.
5. Obstetric shock is rare.
6. Pulmonary complications are rare.
7. Postoperative discomfort is absent.

For the physician

1. The technique of its use is simple.
2. It may be used when skilled anesthetists are not available.
3. It affords maximal relaxation of the pelvic muscles.
4. No additional anesthesia is needed for repairs.

The contraindications to spinal anesthesia are:

1. Cases in which the central nervous system or spinal disease interferes with aseptic technique.
2. Abnormal presentations.
3. Blood pressure below 100 mm. of mercury.
4. Acute shock.
5. Acute heart failure.
6. Constriction ring dystocia.

J. ROBERT WILLSON, M.D.

NEWBORN

Wilwell, G. B. Anemias of the Newborn. *Cesal. M. Ass. J.* 1945 33 555.

Anemia is defined as any state in which the hemoglobin is less than normal in proportion to the blood volume. This state can arise from several causes such as blood loss, failure of cell formation or hemoglobin, excessive cell destruction or combinations of these.

These anemias are reviewed under four headings:

Anemia due to hemorrhage. Hemorrhage may be suspected if the red cells drop to 4,000,000 with a corresponding reduction in hemoglobin. It is a hypochromic type becoming microcytic if the loss continues. Nucleated red blood cells appear and the reticulocytes increase. The leucocytes increase to from 20,000 to 30,000 and the platelet count is normal or raised.

Traumatic hemorrhage usually occurs in the first two days and may be severe enough to cause anemia.

The two most common diseases of the newborn giving rise to spontaneous hemorrhage are:

Hemophilia which is rare. The clotting time may be prolonged for hours but the blood eventually clots. Treatment consists of frequent transfusions.

Hypoprothrombinemia. This is very important and takes the form of constant oozing. It usually appears between the second and eighth day. Marked increase in the prothrombin time alone characterizes this condition. Vitamin K administration to the mother in labor or intramuscular injection of the newborn is remarkably efficacious in preventing or benefiting this condition.

Anemia of infection. The hematopoietic systems of babies vary in their vulnerability to infection. Anemia lowers the resistance to infection and infection aggravates the anemia. Severe pyogenic infections, septicemia, pyelonephritis, and pneumonia may cause a serious drop in hemoglobin. Streptococcal and bacillus coli infections are more likely to cause anemia than streptococcal infections although a hemolytic staphylococcus may cause severe anemia even of an aplastic type.

Congenital syphilis is the chief offender of the chronic infections.

Acute congenital hemolytic anemia may rarely follow infection and sickle cell anemia, occurring only in negroes, may be precipitated by infection.

Repeated transfusion is the treatment of choice and if the anemia persists there has probably been some destruction of the bone marrow.

Anemia of prematurity This type is characteristic of all immature infants and its severity is governed by the state of maturity. The anemia may not reach its maximum for from 8 to 10 weeks and at 3 months a gradual improvement sets in. Various workers have shown that iron is not directly involved in the causation of this anemia. Immaturity of the hemopoietic system makes it difficult for these infants to perform postnatal adjustments and to recover the normal volume of blood and its constituents.

In the early stages it is a normocytic normochromic anemia. Microcytosis occurs later. The prothrombin time is often increased.

These babies are potential bleeders and they require vitamin K more urgently than normal infants. Treatment with iron is of some use only after the third month at which time there is a natural spontaneous tendency toward recovery. Transfusion has only a transitory effect and is used only to combat infection and complications.

Anemias due to hemolysis These are for the most part related to the Rh factor and its workings. The author gives a good review of the mechanism by which Rh incompatibilities cause hemolysis of the blood cells in infants and subsequent anemias. The hemoglobin may fall to 20 per cent and the red blood cells to 1,000,000. The treatment is multiple transfusions of Rh negative blood.

HARRY FIELD, M.D.

MISCELLANEOUS

Tompkins P: The Timing of Ovulation with Basal Temperature Graphs *Med Clin. N. America* 1945 39 1435.

Graphs of the daily basal body temperature have been used by the author as an index to ovulation in

cases of sterility. Special graph paper or improvised paper is suitable. The patient is instructed to take her temperature rectally with an ordinary clinical thermometer each morning upon awakening and before rising drinking eating and smoking. It is to be recorded if any acute infection exists at the same time although marked upper respiratory infections produced practically no change in the rectal temperature. The results of this method concur with the established theory that ovulation occurs on the fourteenth day before the menstrual period regardless of the intervals of the periods.

The time of ovulation is marked by a rise in rectal temperature, which is sustained for several days and is usually preceded by a slight fall in temperature. If intercourse occurs near the time of the temperature shift there will be a better chance of conception than if intercourse occurs only at other times in the cycle. The span during which the ovum is susceptible to fertilization is believed to be from 12 to 24 hours. The author states that the length of pregnancy is 266 days rather than the accepted 280 days.

The reason for the temperature shift is not established. Two suggestions are offered (1) that progesterone elevates the temperature and (2) that during the preovulatory phase the temperature is depressed by estrogens.

The basal body temperature graphs can be used for the following (1) to determine the time of maximum and minimum fertility (2) to determine the time for artificial insemination and endometrial biopsies (3) to aid in securing early human ova (4) to help in evaluating the effectiveness of treatment designed to produce ovulation, especially x ray therapy and (5) in occasional cases to predict the date of delivery. CATHERINE B. HESS, M.D.

for periods which vary from 2 months to a year with no evidence of syphilis.

CATHERINE B. HESS, M.D.

LABOR AND ITS COMPLICATIONS

Resnick, L.: Spinal Anesthesia in Operative Obstetrics. *Br. M. J.* 1945 2 722.

Although the safety of spinal anesthesia for general surgery has been generally accepted its use in obstetrics is still considered dangerous. The author reports a series of 137 cesarean sections and 256 operative vaginal deliveries done under heavy nitroperalin (1 in 300 in 6% glucose in 3 c.c. ampules) spinal anesthesia.

Premedication was given to all women who were to be delivered by cesarean sections. It consisted of omnopon gr 1/3 and scopolamine gr 1/300, given about 45 minutes before operation and in addition, atropine gr 1/100 and ephedrine gr 1 for vaginal deliveries most of them had had some premedication during the labor but were given ephedrine gr 1.

The dosage for cesarean sections varied from 2.5 to 1.5 c.c. of the solution and for vaginal deliveries from 0.5 to 0.8 c.c. which gave anesthesia to just below the umbilicus.

The indications for and the types of cesarean section performed are summarized. 75 percent of the sections were of the lower segment type. Of the 256 vaginal deliveries 136 were made by means of the outlet forceps, 103 by midforceps, 8 by high forceps, 6 by breech extraction and 4 by craniotomy. Rotation of the head was performed 167 times.

No maternal deaths occurred in the cesarean group, while 2 of the patients delivered from below died (one because of pulmonary embolus and the other following sulfonamide therapy for pyelitis) in neither case was the anesthesia responsible for the death. Seven (5%) of the cesarean babies and 34 (13%) of those delivered from below died, but none of these deaths could be attributed to the anesthesia.

The author considers the following to be the advantages of spinal anesthesia:

For the mother

1. It is safe when inhalation anesthesia is contra indicated.
2. It is safe in pre-eclampsia and eclampsia.
3. It is safe in essential hypertension.
4. Uterine atony and hemorrhage are rare.
5. Obstetric shock is rare.
6. Pulmonary complications are rare.
7. Postoperative discomfort is absent.

For the physician

1. The technique of its use is simple.
2. It may be used when skilled anesthetists are not available.
3. It affords maximal relaxation of the pelvic muscles.
4. No additional anesthesia is needed for repair.

The contraindications to spinal anesthesia are:

1. Cases in which the central nervous system or spinal disease interferes with aseptic technique.
2. Abnormal presentations.
3. Blood pressure below 100 mm. of mercury.
4. Acute shock.
5. Acute heart failure.
6. Constriction ring dystocia.

J. ROBERT WILLIAMS, M.D.

NEWBORN

Wiswell, G. B.: Anemia of the Newborn. *Canad. M. Ass. J.* 1945 53:555.

Anemia is defined as any state in which the hemoglobin is less than normal in proportion to the blood volume. This state can arise from several causes such as blood loss, failure of cell formation or hemoglobin, excessive cell destruction, or combinations of these.

These anemias are reviewed under four headings.

Anemia due to hemorrhage. Hemorrhage may be suspected if the red cells drop to 4,000,000 with a corresponding reduction in hemoglobin. It is a hypochromic type becoming microcytic if the loss continues. Nucleated red blood cells appear and the reticulocytes increase. The leucocytes increase to from 20,000 to 30,000 and the platelet count is normal or raised.

Traumatic hemorrhage usually occurs in the first two days and may be severe enough to cause anemia.

The two most common diseases of the newborn giving rise to spontaneous hemorrhage are:

Hemophilia which is rare. The clotting time may be prolonged for hours but the blood eventually clots. Treatment consists of frequent transfusions.

Hypoprothrombinemia. This is very important and takes the form of constant oozing. It usually appears between the second and eighth day. Marked increase in the prothrombin time alone characterizes this condition. Vitamin K administration to the mother in labor or intramuscular injection of the newborn is remarkably efficacious in preventing or benefiting this condition.

Anemia of infection. The hematopoietic systems of babies vary in their vulnerability to infection. Anemia lowers the resistance to infection and infection aggravates the anemia. Severe pyogenic infections, septicemia, pyelonephritis, and pneumonia may cause a serious drop in hemoglobin. Streptococcal and bacillus coli infections are more likely to cause anemia than streptococcal infections although a hemolytic staphylococcus may cause severe anemia even of an aplastic type.

Congenital syphilis is the chief offender of the chronic infections.

Acute congenital hemolytic anemia may rarely follow infection, and sickle cell anemia, occurring only in negroes, may be precipitated by infection.

Repeated transfusion is the treatment of choice and if the anemia persists there has probably been some destruction of the bone marrow.

Anemia of prematurity This type is characteristic of all immature infants and its severity is governed by the state of maturity. The anemia may not reach its maximum for from 8 to 10 weeks and at 3 months a gradual improvement sets in. Various workers have shown that iron is not directly involved in the causation of this anemia. Immaturity of the hemopoietic system makes it difficult for these infants to perform postnatal adjustments and to recover the normal volume of blood and its constituents.

In the early stages it is a normocytic normochromic anemia. Microcytosis occurs later. The prothrombin time is often increased.

These babies are potential bleeders and they require vitamin K more urgently than normal infants. Treatment with iron is of some use only after the third month at which time there is a natural spontaneous tendency toward recovery. Transfusion has only a transitory effect and is used only to combat infection and complications.

Anemias due to hemolysis These are for the most part related to the Rh factor and its workings. The author gives a good review of the mechanism by which Rh incompatibilities cause hemolysis of the blood cells in infants and subsequent anemias. The hemoglobin may fall to 20 per cent and the red blood cells to 1,000,000. The treatment is multiple transfusions of Rh negative blood.

HARRY FIELDS, M.D.

MISCELLANEOUS

Tompkins, P: The Timing of Ovulation with Basal Temperature Graphs. *Med Clin N America*, 1945 29 1485.

Graphs of the daily basal body temperature have been used by the author as an index to ovulation in

cases of sterility. Special graph paper or unprovided paper is suitable. The patient is instructed to take her temperature rectally with an ordinary clinical thermometer each morning upon awakening and before rising, drinking, eating, and smoking. It is to be recorded if any acute infection exists at the same time, although marked upper respiratory infections produced practically no change in the rectal temperature. The results of this method concur with the established theory that ovulation occurs on the fourteenth day before the menstrual period, regardless of the intervals of the periods.

The time of ovulation is marked by a rise in rectal temperature, which is sustained for several days and is usually preceded by a slight fall in temperature. If intercourse occurs near the time of the temperature shift there will be a better chance of conception than if intercourse occurs only at other times in the cycle. The span during which the ovum is susceptible to fertilization is believed to be from 12 to 24 hours. The author states that the length of pregnancy is 266 days rather than the accepted 280 days.

The reason for the temperature shift is not established. Two suggestions are offered: (1) that progesterone elevates the temperature and (2) that during the preovulatory phase the temperature is depressed by estrogens.

The basal body temperature graphs can be used for the following: (1) to determine the time of maximum and minimum fertility; (2) to determine the time for artificial insemination and endometrial biopsies; (3) to aid in securing early human ova; (4) to help in evaluating the effectiveness of treatment designed to produce ovulation, especially x-ray therapy; and (5) in occasional cases to predict the date of delivery. CATHERINE B. HERR, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Peters, J. T.: Origin and Development of a New Therapy for Crush Injury Transfusion Kidney and a Certain Number of Other Diseases. *Acta med. scand.* 1945 123 90.

Considering the fact that a part of the kidney function is a mechanical filtration process the author constructed an artificial nephron of glass and rubber. By means of this apparatus it could easily be demonstrated that not only oliguria and anuria but also polyuria could be imitated by a purely mechanical device. The imitation anuria was produced without any obstruction, as a result of increased intrarenal pressure which caused a decrease of the effective filtration pressure.

The presence of an increased intrarenal pressure in vivo is readily deduced from certain pathological findings. Thus the obstruction of the tubules by blood clots, cell detritus and crystals is often found at autopsy to be present only in a small part of the kidney or it is altogether absent. An obstruction, therefore is unnecessary for the development of anuria.

In mercury poisoning crush injury transfusion kidney and several other diseases oliguria or anuria associated with hyperazotemia and uremia is the important syndrome. For the treatment of these conditions, decapsulation of the kidney is recommended, on the assumption that the condition is the result of increased intrarenal pressure. This should be considered an emergency operation, and should be done on the first day that the syndrome develops.

Uremia caused by glomerular destruction, however must be sharply differentiated from the uremia caused by increased intrarenal pressure. The former cannot be cured by lowering the intrarenal pressure by a few millimeters of mercury. In the latter decapsulation, diuretics and pressor drugs are now widely used either separately or in combination, and apparently with success. SAMUEL KARW M.D.

Abramson, D. J.: Renal Typhoid Fever; Presentation of a Case of the Primary Type. *J. Urol. Balt.*, 1945 54 432.

A case of primary renal typhoid is presented. It is of additional interest because of the presence of calculi and pyelonephrosis. Enteric typhoid had been consistently excluded by negative clinical findings, Widal tests, and stool and blood cultures.

Emphasis is placed on the necessity of careful bacteriological examinations of routine urinary cultures, the lack of significance of Widal tests in previously immunized individuals and the value of conservative treatment. The role of sulfonamides in renal typhoid deserves further study.

Both primary and secondary renal typhoid are discussed. The epidemiological significance of ty-

phoid disease of the kidney and of the carrier state is emphasized. JOHN A. LOFF M.D.

Jacobs, A.: Tuberculous Disease of the Kidney. *Glasgow M. J.* 1945, 144:161.

The author presents a set of concepts for dealing with tuberculous disease of the kidney based on a series of over 250 nephrectomies and a further untotaled series of unoperated cases of renal tuberculosis. He divides the disease into three main clinical groups: tubercle bacilluria without urinary symptoms; renal involvement with signs and symptoms confined solely to the urinary tract and no other obvious tuberculous focus; and renal involvement appearing subsequent to the occurrence of an extra renal lesion.

Tubercle bacilluria according to the author requires only follow-up urological examination. In many cases the minute renal lesions accounting for the bacilluria will heal. In others, the microscopic foci will progress and the second clinical condition will develop: that of obvious renal involvement. In unilateral disease nephrectomy is indicated. In bilateral involvement the operation is contraindicated unless the involvement on one side is minimal and it is believed that removal of the badly infected kidney will materially improve the patient's general condition. In cases of renal tuberculosis complicated by extrarenal foci the more serious life taking lesions are granted precedence in the institution of treatment.

Intractable tuberculous cystitis, which has failed to show improvement over a reasonable period of time following nephrectomy will require diversion of the urinary stream by nephrostomy, cutaneous ureterostomy or transplantation of the ureter into the bowel. CLARENCE V. HODGES, M.D.

Ladewig, P., and Eser, S.: Malignant Tubular Adenoma in a Horseshoe Kidney; Its Significance with Regard to General Cancer Pathology. *J. Path. Bact. Lond.*, 1945, 37 405.

A case of malignant tubular adenoma arising within a horseshoe kidney is described by the authors and discussed with regard to its bearing on general cancer pathology. It is concluded (1) that the tubular adenoma ought to be regarded as a cancer matrix according to Cohnheim's theory of displaced embryonic tissue (2) that such displaced embryonic tissues as well as hyperregenerative hormonal and other tissue disturbances merely provide zones of potential growth instability (3) that in these zones "irritation" in the widest conception of the term may induce the fatal event of the cancer cell's birth as a somatic mutation and (4) that Cohnheim's theory and the "irritation" theory of cancer are not mutually exclusive but complementary.

The most widely accepted view is to regard the tubular adenoma as the result of an abnormality in fetal development at the time when the ureteric bud joins up with the metanephrogenic blastema and induces its differentiation and growth. In this stage certain elements of the tissues involved may fail to establish contact and become excluded from the co-ordination of further development. They are left free to unfold their remaining growth potency in unusual ways. This theory finds support in the authors' case from the peculiar combination of adenoma and horseshoe kidney. It is in fact generally agreed that horseshoe kidney is due to unusual growth impulses of the metanephrogenic tissues whereby the bilateral blastemas come into collision. In view of this the authors believe that they can accept the dysontogenetic nature of the tubular adenoma.

The tubular adenoma with its dysontogenetic origin is only a peculiar ground on which the malignant change has taken place. In the same way adenoma of the cirrhotic liver predisposes to malignancy as do adenoma of the prostate, certain forms of adenoma of the female breast and in rare instances adenoma of the thyroid gland. The cause of the formation of these different adenomas is the potentiality for prospective growth in existent embryonic tissue, hyperregenerative power in impaired tissue or even unbalanced hormonal stimulation. But none of these can be regarded by themselves as responsible for the induction of malignancy. This is shown by the uneven ratio between the frequent occurrence of adenomas and the relatively rare incidence of their malignant transformation. Moreover, in accordance with recent research on the subject we are justified in assuming that spontaneous cancer development is the result of an incidental and peculiar combination of various factors and influences, no one of which necessarily bears directly and specifically on the final result.

JOSEPH E. NARAT M.D.

Bowie, C. F., and Bora, E.: Primary Carcinoma of the Ureter. *J. Urol. Balt.* 1945 54 434.

Primary carcinoma of the ureter can still be considered a rare tumor although an increasing number of cases have been reported during the past decade. The total number of reported cases up to date is 175.

A case of carcinoma of the ureter complicated by severe infection which made the diagnosis more difficult, is reported. The operative technique is reported in detail because certain well recognized general surgical principles used in attacking malignant tumors anywhere else in the body were employed. No priority is claimed on the technique.

The principles carried out in this case were (1) opening of the peritoneal cavity for evidence of spread of the tumor (2) beginning dissection in healthy tissue above the tumor and (3) after the tumor was reached from above, dissection on the bladder side with the electrosurgical knife the whole

tumor being removed en masse. The kidney and remaining portion of the ureter were removed 4 months later. No evidence of tumor was present. Cystoscopy revealed a normal bladder with no evidence of recurrence.

JOHN E. KIRKPATRICK M.D.

BLADDER, URETHRA, AND PENIS

Krafka, J. Jr.: The Elasticity of the Human Urinary Bladder. *J. Urol. Balt.* 1945 54 438.

Incidental to studies made on the elasticity of the human aorta tests were run on the elongation of standard strips of urinary bladder. The technique used was that previously described in which increasing weights applied by the gravity pull on a carriage running on an inclined plane, exert a stretching force on the specimen and automatically record the relationships. The machine used was the Scott scigraph, which is commonly employed in fabric laboratories for measuring the elasticity and the tensile strength of thread.

It is common textbook knowledge that the detrusor serves as the principal agent in the emptying of the bladder. The urologists are also aware of the character of the pressure curves developed during the filling of the bladder. The commonly accepted value for emptying of the bladder is between 20 and 40 mm. Hg upon which is superimposed an additional volitional pressure produced by contractions of the abdominal muscles and the descent of the diaphragm which brings the total intravesicular pressure to approximately 74 mm. It is also observed that the pressure developed upon the addition of successive increments of fluid to the bladder volume is initially high but immediately levels off to fixed values proportional to the volumes prevailing. These reactions are commonly interpreted as due to balance in muscle tonus and the primary and secondary pressures are used as indications of hypertonicity or atony in various pathological states.

That such pressures prevail at other sites in the body has been well established. Hamilton, Woodbury, and Harper (1936) have made a study of cough and strain upon the blood pressure and upon the cerebrospinal fluid. Intracranial pressure may be raised 50 mm. Hg and there is one record of a blood pressure of 380 mm., due to strain.

Woodbury, Hamilton and Torpin (1937) in an analysis of intraterrine pressure have shown that 70 mm. pressure can be transmitted to the intragastric pressure and a like equivalent to the pregnant uterus.

Muschat (1935) noted a maximum of 60 mm. Hg pressure in the bladder of the tabetic with a paralyzed bladder wall, but an intact abdomen.

Another concept, of course, would need to be considered in a corollary to the one just developed namely the protection of the ureters against these high intravesicular pressures. Wellenweber has made a study of the pressure prevailing in the kidney pelvis at various intravesicular pressures. The for

mer is always lower than the latter. Thus at 120 mm. bladder pressure the pelvic pressure is 70 mm (water) at 350 it is 200 mm. This factor however is not so significant as the male one since the angulation of the ureter and the muscles of Waldeyer seem to provide a competent mechanism to prevent transmissal of the high pressures to the ureter.

That the musculature of the bladder does maintain a definite tonus is seen in the work of Holmes (1933) on the paralyzed bladder. Injury to the cervical, dorsal, or sacral cord results in an atonic bladder with a characteristic volume pressure relation on filling. His figure 2 shows a definite filling emptying curve which are reciprocals. His figure 7 shows one of the features noted by Langworthy, namely a sharp straight line rise followed by a rapid return to a base line in the course of a few minutes.

The effective stimulus to the emptying of the bladder is commonly assumed to be tension in the bladder wall. Free nerve endings and pressure corpuscles have been described but it is difficult to see how these can in one instance give the sensation of fullness then urgency and lastly pain. If the simple assumption is made that the tonus of the muscle develops and mediates the sensation a reasonable opinion is at hand. Hypertonic bladders empty at small volumes atonic bladders store tremendous volumes of urine either under pathological states or in the last months of pregnancy. Irregular contractions are seen normally at 400 c.c. volume and spontaneous contractions are noted after the steep parts of the cystometrograms curve. Curves are materially affected in the case of megacolon. How these factors could be applied to simple nerve endings or to pressure corpuscles is not clear but they would all be effective in muscle tone. Smooth muscle must act as a sensory ending to mediate its own reflexes either local or central.

The percentage stretch of standard strips of urinary bladder have been measured and Young's modulus calculated. The values range from 0.488 to 4.840 dynes per centimeter square $\times 10^6$.

The elasticity curves for the bladder have been compared to those for the aorta. The character of the curves is essentially different that for the aorta is a geometric curve, for the bladder a straight line curve. Within the limits of the test, the distensibility of the bladder is not checked by collagenous fibers such as are seen in the aorta.

Calculations are presented which equilibrate the stretching forces against manometric pressures as noted in the bladder by other investigators using the cystometer.

The theory of muscle function in the bladder is discussed. The primary function of bladder emptying for the detrusor is accepted. Secondary functions are 3 in number. The first of these is to provide an elastic membrane which can adjust bladder volume to bladder pressure. The second function is to provide a local elastic mechanism to adjust for the accessory pressures impressed on the bladder by cough and strain. The third considers the muscle as

a sensory organ for the mediation of the stress sense as a stimulus to voiding.

JOHN E. KIRKPATRICK, M.D.

GENITAL ORGANS

Heyman, A., Beeson, P. B. and Sheldon, W. H.: The Diagnosis of Chancroid. *J Am M Ass*, 1943 139 935

The methods employed at present for the diagnosis of chancroid are far from satisfactory. Current textbooks indicate that accurate diagnosis can be based on the clinical features, on the results of skin tests, or on the examination of stained smears. Most venereologists, however, know that each of these methods is subject to major limitations and errors. Actually at present the diagnosis is usually based on negative dark field examinations for spirochetes, and on clinical improvement after the institution of sulfonamide therapy. The establishment of reliable criteria for a positive diagnosis of chancroid would unquestionably be of value.

The present article is a report on the relative efficiency and usefulness of a number of diagnostic procedures in chancroid. These findings were obtained during an intensive study of a group of 125 patients suspected of having either chancroid or lymphogranuloma venereum.

A positive diagnosis of chancroid was made in 60 of them. Of the various methods, biopsy appears to be the most efficient single method of diagnosis and can be depended on to give a diagnosis in over 90 per cent of the cases in which it is applicable. Its use is limited to cases in which there are primary genital lesions. The removal of tissue for biopsy is in most instances a simple procedure, well suited to out-patient work. It is undesirable however in patients with small lesions because of the pain involved.

Cultural demonstration of the Dreyer bacillus can be accomplished in at least 75 per cent of all cases. The technique is not difficult and can be carried out by a competent technician. Culture is less likely to be successful in advanced lesions which are heavily contaminated with other bacteria. It is the only means of obtaining a positive diagnosis in patients with buboes but without primary lesions.

Diagnosis by means of direct smears of genital lesions is possible in approximately 50 per cent of the cases. This method has the advantage of simplicity and immediate diagnosis. Unfortunately, it is likely to be useless in advanced lesions, in which there is a heavy growth of other bacteria.

Autoinoculation has several disadvantages and does not take with sufficient frequency to make it of value in routine work.

The skin test for chancroid should never be relied on as the sole method of diagnosis although it may be of limited value as an adjunct to other procedures. In this group of 60 proved cases of chancroid, positive skin tests were found in only 46 (77 per cent). A further disadvantage lies in the fact that a positive skin reaction persists for many years after

GENITOURINARY SURGERY

an infection and therefore may not be significant in reference to the present illness.

The diagnosis of chancroid can in the majority of cases be established by suitable laboratory procedures.

JOHN E. KIRKPATRICK, M.D.

Lazarus, J. A.: The Significance of Spontaneous Hematuria Associated with Hypertrophy of the Prostate. *J. Urol. Balt.* 1945 54 531

Spontaneous hematuria is not infrequently an outstanding symptom among patients with prostatism and in certain instances it may be the chief complaint. The hematuria may vary from the presence of a few erythrocytes to the high power held (occult blood) to massive bleeding which may at times assume alarming proportions. It may be due to the prostate itself or to conditions which are extrinsic to the prostate, such as a cystitis secondary to and aggravated by urinary retention vesical renal, and nteral calculi tumors of the kidney, hydronephrosis and acute or chronic glomerulonephritis.

Since the hematuria is due so commonly to the prostate itself the urologist is frequently too casual in his examination after establishing the presence of a prostatic hypertrophy. If he then proceeds to perform a prostatectomy under the mistaken notion that the bleeding is due to the prostate, when in reality it is due to a coexisting renal tumor or some other condition which is unrelated to the prostate the outcome may be disastrous.

The author is, therefore, of the opinion that a complete urological study is indicated in every case of prostatic hypertrophy with hematuria.

Although many urologists have established an aversion for one reason or another to performing cystoscopic examinations upon their prostatic patients the author believes that cystoscopy should be carried out in these cases whenever it is technically possible. He believes that the cystogram and other indirect methods give inadequate information in addition to providing direct visualization of the vesical neck and lumen, cystoscopy gives the opportunity to catheterize the ureters and to take retrograde pyelograms in the event that no obvious cause for the bleeding can be found in the bladder or in the prostatic urethra.

FREDERICK LIEBERHAL, M.D.

Ferguson J. D. and Pagel W.: Some Observations on Carcinoma of the Prostate Treated with Estrogens, as Demonstrated by Serial Biopsies. *Brit. J. Surg.* 1945 33 132.

The authors carried out repeated biopsies by transurethral resection in a small number of patients with carcinoma of the prostate who had received estrogens for from 6 to 30 months. They distinguish two types of tumors those which arise in atrophic tissue in the posterior lobe of an otherwise normal gland and those which develop secondarily in a gland presenting benign hypertrophy.

The latter are usually latent and are discovered during routine microscopy of the enucleated gland. The former are more common, and have usually extended by the time the diagnosis is made. All of the material studied was composed of this type.

The authors took a careful history studied the urine for infection, tested renal function and repeatedly estimated the serum acid phosphatase. Anteroposterior views of the lumbar spine, pelvis and upper ends of the femurs were taken before and after treatment. Occasionally intravenous urograms were made. Four of the 5 cases were treated with stilbestrol and 1 was treated with dienestrol. The Gershom Thompson cold punch was used and biopsy specimens were taken from the posterior quadrant of the prostatic urethra immediately above the verumontanum. Coagulation hemostasis was used as frequently as possible.

The studies showed that in addition to an apparent reduction in the number of tumor nodules in the later sections there were cellular changes such as a diminution in the size of the nuclei measured quantitatively. There was a regressive change from a more cellular type of growth to a scirrhous form. In later sections there was again a diminution in the size of the cell nuclei with concentration of chromatin pyknosis and vacuolation of the cells.

DAVID ROSENBLUM, M.D.

Moschnt M.: Osteitis Pubis following Prostatectomy. *J. Urol., Balt.* 1945 54 447

The condition described is rather unusual. It was first presented as an entity by Beer in 1924. Since then an occasional report is found under the title of perostitis osteitis pubis or osteochondritis depending on which tissue seems predominately affected. Osteitis pubis appears as a distinct disease entity with a more or less characteristic course having no resemblance to an ordinary pyogenic or tuberculous osteomyelitis. It occurs in a small number of patients following operations upon the urinary bladder especially after prostatectomy. It is an inflammatory process of the bone which begins in the symphysis pubis and gradually involves the pubic ramal all the way down to one or both ischial tubercles. This inflammatory process spreads via the perineal to the variously attached muscles of the pelvis especially the obturator internus and levator ani keeping them in a spastic state. Aschner describes the characteristic clinical picture most graphically. The pain is intense and disabling in its effects. It forces the sufferer to lie down and when down he cannot get up nor turn from side to side, except in fear and agony.

The etiology of this condition is obscure the clinical picture with its symptomatology however is clear and follows a definite pattern. This pattern is practically identical in every case from the onset of the disease until clinical cure ensues the patient going through a period of physical agony lasting from 3 to 12 months. Two cases of osteitis pubis are described in detail and a summary of the few cases

from the literature with a discussion of the etiology, symptomatology, clinical findings, x ray studies, pathology, therapy and prognosis, is also included.

As in every other disease in which the sufferings of the patient are very great and prolonged, various therapeutic agents were tried. The most frequently used therapy was diathermy, baking and massage. None of these therapeutic procedures helped in the slightest. Most patients claimed that the diathermy aggravated their pain. X ray therapy was found useless. Application of a body cast is always suggested by the orthopedic surgeon who believes, and rightly so, that immobilization of the pelvis by a solid body cast will relieve the agony of pain. The patients, however, are very intolerant to a body cast.

It is the author's conviction that the disease is self limited and that surgical intervention is not required, but if an abscess does develop it should of course be properly drained. Penicillin (4,000,000 units) was used in case 1 without any subjective improvement whatsoever but it may have caused the absorption of the inflammatory lump near the scrotum. Sulfa drugs were tried without influencing the condition one iota. Any manipulative procedure to hasten the recovery is strongly contraindicated; it only aggravates the condition and stirs up local trauma, thus actually spreading the disease process and delaying the recovery. In a case reported by Barnes, the patient submitted to the "adjustments" of a chiropractor for several months. The "adjustments" were usually followed by chills and temperature as high as 105, and the patient was told that these reactions were supposed to be very beneficial. The majority of patients become so apprehensive that before long one gets the impression that they are greatly exaggerating their pain. The physician, therefore, is frequently tempted to force early activity and to encourage the patient to get out of bed and move about. The author found such forceful actions detrimental to ultimate recovery which was retarded for many weeks. He states that "whenever such activity is contemplated another x ray study will usually disclose that instead of improvement the process is at its worst and absolute rest is indicated."

Prognosis. The ultimate outcome in all cases is good. There is no spread of the disease to other structures or organs. The only complication is an occasional abscess formation with resituation after drainage. The only demonstrable scar is the complete ossification and ankylosis of the symphysis. This, fortunately, remains symptomless and the patient resumes his normal life.

JOHN E. KIRKPATRICK, M.D.

Bishop, P. M. F.: *Studies in Clinical Endocrinology: The Management of the Undescended Testicle*. Gay's Hist. Rep. Lond., 1945, 94, 12.

The author emphasizes the importance of close co-operation between the endocrinologist and the surgeon in deciding which form or combination of forms of treatment of undescended testicle will be

most effective and states that the decision should be based upon the individual situation present in each case. In his terminology the word "testicle" is used in its literal sense, i.e., a little testis. He describes the mechanism of normal testicular descent as occurring in three stages—abdominal, canalicular and extracanalicular—and extensively reviews the literature to discuss the various causes that have been postulated to account for incomplete descent. These are fetal peritonitis, defective development of the transversalis fascia, intercolumnar fascia, cremasteric fascia or muscle shortening of the cremaster muscle because of too powerful contraction, shortening of the processus vaginalis or of the cord structures, absence of the external ring and absence of the entire inguinal canal including both internal and external rings. Maldescent is often found to be associated with other physical and mental congenital deformities. The incidence of various positions of arrest, as described by various observers, is discussed.

Apart from the mechanical factors incident to body growth that play a role in the normal descent of the testicle, chorionic gonadotropin is a responsible endocrine factor. It causes enlargement of the testicle (indirectly a mechanical factor) stimulates the development of all the connective tissue elements associated with the testicle in its descent, and therefore elongates the cord structures and, by its action on the interstitial tissue of the testicle stimulates the secretion of androgen which "secondarily causes full development of the sexual apparatus, thus assisting the descent of the testicle" (Möllen, d'Armour and Gustavson quoted by the author).

A portion of the author's cases support the somewhat controversial view that androgenesis is affected by maldescent; the author is in full agreement with other writers that spermatogenesis is profoundly affected. He also believes that chorionic gonadotropin, although it may stimulate androgenesis, has no effect on spermatogenesis.

The evidence, both direct and indirect, for spontaneous descent of the testicle after birth is reviewed with the conclusion that it does occur.

Complications and sequelae incident to an descended testicle are pain, vulnerability to trauma, infection, hydrocele, torsion, psychological effects and malignant degeneration. However, endocrine or surgical procedures for inducing descent do not seem to diminish the possibility of malignancy.

From a surgical point of view cases may be classified into three groups.

Surgery of the atrophied testicle. I.e., removal to prevent possible malignant changes, orchidopexy for cosmetic and psychological reasons or either procedure to avoid the liability of trauma or torsion.

Surgery of the testicle with a deviated or impeded descent. In which the problem is purely a mechanical one and consists merely of obviating the difficulty caused by fibrous bands, adhesions, or bursal involvement. The best surgical results are obtained in

this group subject to the author's arbitrary qualification that the patient should not be older than 10 or 11 years

Surgery of the testicle with a delayed descent which is rendered difficult by the problem of preserving the blood supply of the testis

The optimal age for endocrine therapy must be determined because (1) overdosage at an early age may lead to premature puberty (2) the tissues are more responsive at the time of puberty and (3) the longer a testicle is left undescended after spermatogenesis begins, the greater the danger of irreparable damage first to the seminiferous tubules and later to the interstitial tissues. The criterion for dosage is the tendency toward excessive androgenic development. Most authors cited believe that endocrine therapy should not be continued for more than a few months. Abdominal testicles are not likely to respond to endocrine therapy. Canalicular testicles are more responsive in a high percentage of cases (60 per cent in the cases cited by the author) and extracanalicular testicles are difficult to evaluate and are therefore excluded from the author's analysis. Adverse effects of endocrine therapy employed in proper dosage were not noted by the author.

The conclusions derived from this study are (1) the extracanalicular testicle is a surgical problem (2) the canalicular testicle is primarily an endocrine problem and should be treated surgically only after endocrine therapy has failed or when there is a complicating mechanical impidence and (3) the abdominal testicle is unlikely to respond to either method of treatment. CLARENCE V. HODGES, M.D.

Vermaulen C. W. and Hagerty C. S.: Torsion of the Appendix Testis (Hydatid of Morgagni); Report of 2 Cases with a Study of the Microscopic Anatomy. *J. Urol. Balt.*, 1945 54 459.

The observation of 2 cases of torsion of the appendix testis by one of the authors in a limited and brief urological experience led the authors of this article to believe that the condition is perhaps more common than reports would indicate. Unless it is realized that the severity of the symptoms produced by torsion of this minute structure may be out of all proportion to the size of the appendix testis the condition may easily be mistaken for other intra-scrotal diseases, such as acute epididymitis, acute orchitis or torsion of the spermatic cord. In other instances a diagnostic mistake may be made because the initial symptoms sometimes focus attention upon the lower abdomen with little to indicate that the lesion is inside of the scrotum. This occurred in the first case described in this article in which the non-scrotal symptoms and signs confused the diagnosis to the extent that the condition was first called acute appendicitis.

Diagnosis of torsion of the appendix testis may be very difficult. In general the symptomatology is that of torsion of the testis. Both conditions occur chiefly in preadolescent or young adult males. In both attacks of incomplete transient torsion with

slight symptoms may have occurred previous to the acute severe episode. It has been said that torsion of the appendix testis does not result in inflammation of the scrotal skin, while torsion of the testis does produce this condition. However in both of the authors' cases marked erythema and edema of the skin of the affected side occurred.

Except by palpation of the spermatic cord and the scrotal contents it will be impossible to distinguish between torsion of the testis and torsion of the appendix testis. If there is a tender mass anterior to the testis it may be either the epididymis of a rotated testis or a twisted appendix testis. Differentiation can be made only by careful examination.

The epididymis of a rotated testis would extend down the entire length of the testis while an anterior mass due to torsion of the appendix testis would be limited to its upper pole and be movable upon the testis.

Very little information could be obtained from articles on torsion of the appendix testis regarding the usual histological appearance of this small structure. Furthermore textbooks on histology give descriptions that are not entirely in accord. For example Bailey's *Textbook of Histology* states that the appendix testis (hydatid of Morgagni) is a vesicular structure lined by simple columnar epithelium surrounded by vascular connective tissue. Maximow and Bloom say that the appendix testis is a small nodule consisting of vascular connective tissue and lined with columnar, sometimes ciliated epithelium. Lowley and Kirwin state that the hydatid of Morgagni is a pedunculated pear-shaped sac from one-eighth to one-third inch long its free extremity dilated and containing a colorless fluid. The lack of information on the histological structure in case reports of torsion of the appendix testis and conflicting reports on the histological picture as described in textbooks prompted the study of 28 appendices testes from the standpoint of their gross and microscopic anatomy.

Grossly the appendix testis is a small ovoid or flattened tab of pale gelatinous tissue varying from 1 mm. to 1.0 cm. in diameter. It is attached to the tunica albuginea by a short pedicle. In at least half of the specimens examined, the pedicle was sufficiently long and narrow so that it could have undergone torsion.

Microscopically the appendix testis was made up of loosely arranged connective tissue which was moderately rich in blood vessels. In the connective tissue of some specimens were seen spaces of varying size apparently lined with endothelium and frequently containing a precipitated albuminous material. These structures had more the appearance of lymph channels than that of remnants of epithelial lined tubules. Most of the specimens had a few scattered leucocytes in the tissues. All of the appendices testes were covered by tall columnar epithelium which was sometimes ciliated and associated with the columnar epithelium were a few

round pale mucous secreting cells. This epithelium became continuous with the very flat columnar epithelium of the tunica albuginea.

Epithelial inclusions were present in 2 of the 28 specimens. The epithelial covering of the appendix testis and the lining of the epithelial inclusions closely resembled the lining of the distal end of the fallopian tube of the female. This would be expected because the appendix testis is derived from the cranial end of the muellerian duct which in the female forms the fimbriated end of the fallopian tube.

JOHN E. KIRKPATRICK, M.D.

Francis, R. S.: The Status of Hormonal Bioassay in Malignant Disease of the Testicle. *Brit. J. Surg.* 1945 33 175.

With the exception of the seminoma, which is considered to be derived from the spermatogenic tubule cells, testicular tumors have come to be denoted by the name "teratoma" and other names depending upon the type of tissue which predominates have been applied to this group, such as chorioepithelioma, embryonal adenocarcinoma, teratoid carcinoma with cancerous elements and "mixed adult types with carcinoma."

In 1930 Zondek discovered that malignant tumors of the testis caused the urine to give a positive Aschheim-Zondek pregnancy test. In the test and in a male's ovary three results were obtained: (1) ripening of the graafian follicle, (2) hemorrhage into the cyst, and (3) gross enlargement of the uterine horns. It is now understood that the hormone output tends to vary indirectly with the degree of cellular maturity of the tumor. However, one cannot foretell the histological type of tumor from bioassay of the tumor alone. There is a correlation between the hormone levels and the clinical course and consistent high levels usually lead to a fatal outcome. It must be pointed out that many negative assays have been associated with malignancy.

The test is a valuable indication of the effectiveness of treatment. When the hormone output falls to 400 mouse units per liter within two weeks of the completion of treatment, the prognosis is good. A rising or stationary titer after treatment is a bad omen. It is due to local recurrence or metastasis.

The test has various limitations such as variations of methods of extracting urine, the numbers of mice used per level of assay, variations in the interpretation of ovary changes, and the original names of tissues present which give rise to increased hormone output. In the present stage of the test, the assay of the urinary hormones is not a basis for attempting to foretell the histological type of tumor. There is some evidence that the seminomas produce only follicle stimulating hormone and that embryonal teratomas produce both follicle and lutein stimulating hormone (chorionic hormone). Simple orchiectomy is the operation of choice, followed routinely by irradiation, especially of the aortic glands, whether or not metastases are suspected. This routine would cause fibrosis of the lymph-

drainage system and prevent the spread of a possible local recurrence subsequent to treatment.

There is need for a standardized technique of extracting hormones taking 24 hour specimens, making routine assays before treatment and serially during and after treatment using more than 1 mouse per level of concentration, making histological section of the mouse ovary after the test, and making bioassay of the tumor with determination of the two hormones separately. While the range of titer is characteristic for the three main groups—the embryonal teratoma, the seminoma, and the mixed adult teratoma—the precise pathology of a particular tumor cannot be predicted from the preoperative urinary assay, although low levels suggest either seminoma or the mixed adult type. Follow up tests should be performed for at least 10 years after treatment—first weekly then at less frequent intervals, and then at six month periods.

MISCELLANEOUS

Borhans, R. A.: Treatment of Orchitis of Mumps. *J. Urol.*, Balt., 1945 54 547

The so-called entity "orchitis of mumps" is a monomer. It has been considered an infection or inflammation involving the testes. In a naval hospital it was observed that the patients do not develop primarily an orchitis of mumps but an acute hydrocele around the testicle which causes a strangulation of the testicle, in contradistinction to a slow forming hydrocele. This acute process causes strangulation, acute inflammatory edema, and ultimate fibrosis and atrophy of the testes. These facts have been substantiated at operation.

During the acute scrotal involvement of mumps there is a high fever and leucocytosis, but after from 12 to 24 hours the damage has been done even though the temperature subsides.

If a small scrotal incision is made during the acute orchitis an acute hydrocele is encountered in which the fluid in the tunica vaginalis is under extreme pressure and has a viscid yellowish color. After drainage no other treatment is necessary and the fever stimulates a crisis of pneumonia. If drainage is delayed, the tension in the hydrocele lessens, the testicle becomes blackish and the testicular tissue presents bulbous edema and inflammation.

In early cases of orchitis of mumps incision of the acute hydrocele with removal of the drain in 48 hours is indicated and in late cases, the tunica preputia and albuginea should also be drained. Pentothal sodium anesthesia has proved most satisfactory but local anesthesia has not, as the involved area is tender.

DAVID ROSENBLUM, M.D.

Cook, E. N., and Keating, F. R. Jr.: Renal Calculi Associated with Hyperparathyroidism. *J. Urol.*, Balt., 1945 54 55

Since only 4 cases of proved hyperparathyroidism were observed at the Mayo Clinic from 1929 to

1933 and since this incidence was at a variance with the experience of Albright and his associates who accumulated 67 cases in 10 years the authors made a deliberate search for the disease in the material of the Mayo Clinic from January 1933 to July 1934. They discovered 18 cases. In 4 of these the patients had only the classical disease of the bone which is observed in hyperparathyroidism while in 14, associated renal calculi were demonstrated and evidence of disease of the bone was minimal or absent.

During this same period 850 cases of urinary calculus were seen. Although this would indicate an incidence of 2 per cent of hyperparathyroidism in cases of urinary calculus, the authors believe that this figure is far too low since only a relatively small proportion of these patients were subjected to a sufficiently careful metabolic study to exclude hyperparathyroidism completely.

A hyperfunctioning parathyroid adenoma was demonstrated in all of the 18 cases of hyperparathyroidism.

The frequency with which the diagnosis is made correctly will vary directly in proportion to the thoroughness with which a search is made for the disease. The greatest opportunity for establishing such a diagnosis will appear in cases of multiple or recurrent calculi. Approximately 10 per cent of urinary calculi will recur following surgical removal. The authors believe that this percentage can be reduced appreciably if the presence of hyperparathyroidism is carefully excluded.

The diagnostic criteria of hyperparathyroidism are hypercalcemia, hypophosphatemia, hypercalciuria and hyperphosphaturia. Frequently repeated examinations are often necessary to establish a diagnosis. Roentgenological findings may be helpful in cases with associated disease of the bone. In cases in which there is uncertainty the authors frequently rely upon quantitative determinations of the calcium in the urine while the patient is on a diet low in calcium.

When calculi are present the symptoms are identical with those occurring with calculi due to other causes. In all such cases a detailed urological study is indicated. It is usually advisable to remedy the hyperparathyroidism first, as subsequent calculi may develop rapidly. It may however be necessary

to take care of the urological problem first because of its acute character.

Many forms of medical therapy have been tried. Diets low in calcium are unlikely to alleviate the renal symptoms and subject the skeleton to the hazard of demineralization. Diets high in calcium increase the tendency toward stone formation. Acidifying drugs such as ammonium chloride are of little avail because the increased solubility of calcium in an acid urine is counteracted by a resulting increased output of calcium in the urine.

The treatment of hyperparathyroidism is surgical, by removal of the offending parathyroid adenoma, or when primary hypertrophy of all parathyroid tissue is involved, by subtotal resection of the parathyroid glands. The urinary calculi already present usually remain unchanged, but in a few instances they have eventually dissolved.

FREDERICK LIEBERMAN, M.D.

Hellendall, H.: Experimental Transmission of Lymphogranuloma Venereum Virus through the Placenta. *Am J Surg* 1945 70 320.

Since it is known that the virus of lymphogranuloma venereum can invade the blood stream, the author attempted to determine if lymphogranuloma venereum can be transmitted through the placenta to the fetus. In 1936 a positive Frei reaction in a 14 day old infant was observed by Dick. The author's studies in 1945 showed that the antigen prepared from the fetal brains of mice gave positive intradermal reactions.

The present work was concerned with three questions: (1) Can the previous work with mice be confirmed with Frei tests in human beings? (2) Can the initial elementary bodies of the lymphogranuloma virus be found in smears and tissues of the fetal brain? and (3) Will antigens from the brain of an intracerebrally infected mouse give a positive Frei test when injected into the skin of an apparently healthy offspring of an infected mother?

The conclusion was reached that lymphogranuloma virus is transmitted through the placenta to the newborn before delivery. The clinical question as to whether there is any occurrence of congenital lymphogranulomatosis in human beings should be studied with a great amount of statistical material.

DAVID ROSENBLUM, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Meyerding, H. W.: Chronic Sclerosing Osteitis.
West. J. Surg. 1945 53: 413.

The patients included in this series of 80 cases of chronic sclerosing osteitis were of the average age of 25 years, appeared to be in good health, and were not disabled. The preoperative clinical laboratory findings of the blood and urine were of little value in the diagnosis. Trauma may have been an inciting factor of the condition in 31.2 per cent of the cases.

The outstanding symptom was persistent localized pain in 93.8 per cent of the cases. In 67.5 per cent this was associated with swelling. The duration of the symptoms averaged 1.4 years. Sixty five per cent of the patients were males. In 92.5 per cent of the cases the lesions were located in the lower extremity, 50 per cent occurred in the middle third of the shaft of a long bone, 90 per cent occurred in the shaft of the tibia or femur. Patients aged from 10 to 30 years comprised 69 per cent of the total number.

The roentgenograms revealed dense spindle shaped cortical regions of sclerosis that involved the shaft of the long bones. Translucent regions, small and round, or oval, were often visible. These regions sometimes showed staphylococci on bacteriological examination of the material removed at operation and have been looked on as foci of infection producing the sclerosis.

The treatment is surgical excision and the results obtained are good.

Compere, E. L., Schulte, W. J., and Cattell, L. M.:
The Use of Penicillin in the Treatment of Acute
Hematogenous Osteomyelitis in Children. *A. A. Surg.* 1945 1: 954.

This is a report of 12 consecutive cases of acute hematogenous osteomyelitis in children ranging from 3 to 12 years of age which were treated with penicillin.

Ten of the cases had been resistant to sulfonamides and only 4 required surgery. There were no deaths.

The authors state that penicillin appears to be more effective in the treatment of acute hematogenous osteomyelitis than any other therapeutic agent including the sulfonamides.

Adequate doses of penicillin, from 15,000 to 30,000 units administered every 3 hours day and night, may not only cure the initial infection but prevent spread to other bones and in most of the cases they make surgery unnecessary. If the treatment is started late, bone damage may call for late surgery.

Medical care must not be neglected in these cases. The fluid balance of the body must be maintained with normal saline solution, glucose, blood or plas-

ma. Splints, plaster casts or traction are used when indicated.
DANIEL H. LEVENTHAL, M.D.

Mardettoll, O. R.: Osteoarticular Lesions in Brucellosis (Lesiones osteoarticulares de la brucelosis). *Rev. Méd. Rosario* 1945 35 8.

Osteoarticular lesions observed in the course of evolution of brucellosis are characterized as is the disease itself by clinical manifestations of various forms. There are many transitional forms between monoarticular and generalized polyarticular lesions. From the physiopathological viewpoint the syndrome may be divided into two classes: (1) allergic manifestations of the early periods of the disease, chiefly in the form of hyperergic reactions of mesenchymal osteoarticular tissues and (2) processes confined to one articulation or one osteoperiosteal segment, which are the sequelae of the accumulation of specific bacilli. Only the last mentioned group represents the authentic lesions of brucellosis.

Two groups of osteoarticular lesions may be distinguished: osseous and articular.

Osseous lesions in brucellosis are relatively rare and occur approximately in 5.8 per cent of all patients if the spinal column is excluded. From the anatomoclinical point of view two conditions may be distinguished, osteoperiostitis and osteomyelitis. The first mentioned condition may assume a simple form of reaction or may develop into a suppurative lesion. A simple reaction is characterized by pain and roentgenological findings, while suppurative conditions have a chronic evolution. Osteomyelitis may appear in an acute or chronic form. Osseous lesions produced by brucellosis are relatively benign and show a rapid tendency toward regression and reparative processes. Various types of chronic osteomyelitis such as pseudotumoral, condensing, or inflammatory have been described. The diagnosis may be difficult if the involvement of the bones appears in very early stages of the disease.

Articular lesions appear in approximately 40 per cent of all cases of brucellosis. They may assume two forms: pseudorheumatism and arthropathies. The first mentioned condition appears nearly exclusively in the acute periods of the disease and may be interpreted as an allergic reaction of the articular mesenchyma to the infection and the toxic effects of brucellosis. The condition may be monoarticular or polyarticular. Arthropathies may be classified as synovitis, arthritis and osteoarthritis. Brucellosis shows a preference for primary localization in the osseous epiphyses, invading the articulations secondarily. As a rule large articulations are affected. Generally articular lesions of brucellosis are relatively benign and no important anatomic or functional sequelae are recorded. Occasionally an ankylosis may develop. Involvement of the spine has been found in as many as from 50 to 75 per cent of all

autopsies of patients suffering from brucellosis. As a rule spondylitis appears in relatively late stages of brucellosis. Various distinct processes develop within the spinal column viz. degenerative destructive and reparative. The process may involve intervertebral discs. Three forms may be distinguished (1) generalized or circumscribed spondylitis, (2) a condition resembling Pott's disease and (3) a spondylarthritic form. The symptoms are those of an involvement of the spine due to any cause namely pain muscular contractures deformities, and the formation of abscesses. There are no characteristic roentgenological signs. Frequently osteophytic and exostotic formations are visible. The process is relatively benign.

The treatment should be directed toward the etiology. Spondylitis requires immobilization on Bradford's frame or in a plaster-of-Paris cast. Albee's operation may be considered if spondylitis is circumscribed and if an intervertebral disc is involved. Social economic and personal problems should be taken into consideration when a prolonged immobilization is contemplated.

JOSEPH K. NARAT, M.D.

Soule, A. B., Jr. Mutational Dysostosis (Cleido-cranial Dysostosis). *J Bone Surg.* 1946 28: 81

Mutational dysostosis frequently transmitted by parents to offspring is characterized by multiple variable skeletal anomalies. The most prominent and frequent of these are aplasia of the clavicles, irregularities of dentition and structural abnormalities of the jaws, skull, vertebrae, pelvis, femora, scapulae, metacarpals, metatarsals and phalanges.

A careful survey of the English literature establishes that the first authentic case was reported in 1870 and since then the author collected cases total 323 of which 198 are familial, involving 52 families. About half of the patients are males. Geographic distribution represents every continent. In the cases with a hereditary background there has been transmission by male and female to a nearly equal degree. The condition may appear in several successive generations and then be lost and apparently not reappear in subsequent generations.

The etiology is associated with a defect in the parental germ plasma so that the anlage of the affected bones, both membranous and of chondral origin is thought to be faulty. Various other theories and observations are presented, none is conclusive. Most of the skeletal defects found in mutational dysostosis are present at birth but may not be obvious until the child develops. The possible variants are so great that no one abnormality is characteristically found in all cases.

A comprehensive discussion of the abnormalities possible in this condition is given and illustrated with photographs and roentgenograms. The dental defects with their complications are most troublesome, and treatment in general is directed toward the alleviation of symptoms. Six cases, two pairs of which were related are presented fully and demon-

strate the variability of the defects. The multiplicity of defects which may occur in this condition makes it rational that the term cleidocranial dysostosis be replaced by the more accurate and descriptive term mutational dysostosis.

FRANCIS E. BRENNECKE, M.D.

Smith F. M.: Late Rupture of the Extensor Pollicis Longus Tendon following Colles' Fracture. *J Bone Surg.* 1946 28: 49

Late rupture of the extensor pollicis longus tendon following Colles' fracture is an unusual complication which results in disability that may be relieved only by operation on the tendon. The author has observed and treated 5 cases of this type on the Fracture Service of the Presbyterian Hospital, New York. These cases are described in detail with illustrations.

The complication has been previously described in the literature and the incidence was given as 1 to 270 Colles' fractures. At the Presbyterian Hospital, New York, the incidence was 1 to 268. The majority of the ruptures have occurred in the left wrist and 4 of the 5 cases reported were in the left wrist. The complication is more frequent in females (60 per cent) and all 5 of the reported cases were in females. The tendon rupture is more common after the age of 30 years and the age incidence in this series was from 21 to 65 years of age.

The cause of the rupture has not been definitely established but it probably follows rather late after acute or chronically repeated trauma. Factors such as partial laceration of the tendon by a spicule of bone and trauma from forceful reduction of the fracture have been considered. Numerous cases of rupture have been reported when the fracture was minimally displaced or unrecognized and no reduction had been done. In 2 of the 5 cases reported the patients sought treatment late that is 19 days and 2 months respectively after their falls. Neither patient suspected she had a fracture and since in neither case had the fracture been reduced or the wrist splinted it was impossible to consider rough manipulation or faulty splints as a predisposing cause of the tendon rupture. In the 3 other cases the latent period of tendon rupture was 25 days, 27 days, and 6 weeks. From the operative and pathological findings in the 5 cases it is the author's belief that in rupture following Colles' fracture the cause is an aseptic necrosis due to interference with the blood supply of the tendon at the distal end of its groove on the radius.

There are no symptoms prior to rupture which would lead the surgeon to suspect a degenerative process in the tendon. A few patients describe a single sharp pain when the tendon ruptures but most of them describe what they call a sensation of something giving way or a snap on the back of the wrist followed by inability on their part to straighten or to lift the thumb actively. They may also note difficulty in picking up small objects such as pins. No subjective sensory changes are noted.

Physical examination reveals first, a thumb that droops in its entirety, and second, partial flexion of the distal phalanx. There is inability to elevate the thumb actively to the same level as the other metacarpals, and it is impossible for the patient to extend the distal phalanx actively against resistance although this can be done passively. The ulnar border of the anatomical snuffbox is characteristically absent. Occasionally the swollen degenerated end of the distal portion of the ruptured tendon can be felt beneath the skin and subcutaneous tissue as a small bump. There is no loss of skin sensation over the superficial distribution of the radial nerve.

The site of rupture in the extensor pollicis longus tendon is usually at the level of Lister's tubercle on the dorsum of the lower extremity of the radius. The distal portion of the ruptured tendon is usually drawn downward and the proximal portion usually retracts upward to the upper edge of the dorsal radiocarpal ligament or even more proximal to this. As much as 5 cm. sometimes separates the two tendon ends. Adhesions occur and the groove on the dorsum of the radius through which the tendon passes becomes obliterated. A specimen stained with Scharlach R showed the presence of fat between the tendon fibers.

In considering the operative repair of this condition, the author emphasizes that the extensor pollicis longus tendon has a dual function. Extension of the distal phalanx upon the proximal phalanx at the interphalangeal joint is probably the less important half of this tendon's function. Drooping of the thumb as a whole which is observed in this complication, is due entirely to the loss of the oblique pull of the tendon. Any operative procedure designed to restore full function must therefore restore the oblique pull. Following experiences of the first 3 cases the author recommends suture of the distal end of the extensor pollicis longus to the extensor carpi radialis longus by end-to-side suture. Following this, the tendon of the extensor pollicis brevis is also drawn over and sutured by a side-to-side suture. The first hookup gives the lift to the thumb and the extensor pollicis brevis adds extension to the distal phalanx. The ideal method of repair by resuturing the tendon ends or by implantation of a free tendon graft is prevented by the adhesions that are present even if they were broken it would result only in bleeding that would produce more and denser adhesions. During postoperative immobilization the tendon would "freeze" and become nonfunctioning. Upon exploration and repair of the tendon the superficial branch of the radial nerve should be isolated and protected because damage to it may lead to distressing numbness of the dorsum of the thumb.

Following operative closure the hand, the wrist and forearm should be immobilized in a volar molded plaster splint in slight cock-up position with the thumb fully extended and elevated. The splint may be removed at the end of 30 days and the patient encouraged to begin moving the thumb very gently in flexion and extension. He should then be advised

to remove the splint 3 or 4 times daily for exercises and for hot soaks. Usually at the end of 3 or 4 weeks it is possible to discard the splint completely at which time the exercises are increased and the patient is encouraged to begin mild active use of the thumb.

In all of the 5 reported cases the patients showed improvement in function and use. The best follow-up results from a functional standpoint were found in the cases treated by the operation proposed by the author.

CHARLES A. WATKINS, M.D.

Guri, J. P.: Pyogenic Osteomyelitis of the Spine. Differential Diagnosis through Clinical and Roentgenographic Observations. *J. Bone Surg.* 1946, 28, 90.

This article is based on 45 cases of pyogenic osteomyelitis of the spine. In order to arrive at the correct diagnosis it was necessary to be very careful in the differential diagnoses. Some of the conditions considered in these diagnoses were acute appendicitis, the meningial syndrome, and the back pain syndrome. The latter was divided into an acute form (16 cases) the subacute form (7 cases) and the insidious form (19 cases). Here the diagnosis rested between the differentiation of pyogenic infection from tuberculosis. The site of the pyogenic infections varied they involved the spinous articular process the transverse process, or the laminae. When pyogenic osteomyelitis involves the vertebral body it may be divided into the localized or diffuse form. When the diagnosis is tuberculosis, in adults, areas of increased density are not frequently found in the roentgenograms of living subjects except when there have been secondary infections huge sequestra, or sudden collapse. There is a definite increase of density and sclerosis in pyogenic spondylitis thus these features are diagnostic and permit the differentiation between tuberculosis and pyogenic spondylitis. RICHARD J. BENNETT JR., M.D.

Hatcher G. H.: The Pathogenesis of Localized Fibrous Lesions in the Metaphyses of Long Bones. *Ann. Surg.* 1945, 12, 1016.

Because of the various secondary characteristics which are prominent in the course of localized benign fibrous lesions of bone, a variety of lesions have been described under various diagnoses. Philip and Burman and Sinberg described the lesions as solitary xanthomas, while Geschickter and Copeland called them variants of solitary bone cysts or benign giant cell tumors. Phemister described some localized non-suppurative lesions of bone as fibrous osteomyelitis. Some of these would now be included in the lesions described as osteoid osteoma. In 1932 Jaffe and Lichtenstein demonstrated the various stages in the development of solitary fibrous lesions of bone and interpreted them as benign tumors formed from mature marrow connective tissue. These were called nonosteogenic fibromas of bone.

The author reports on 51 lesions found in 45 patients and demonstrates the clinical, roentgenologic

ical, and pathological findings in the various stages of the development and regression of the lesion. There were 38 males and 17 females. Five patients had multiple lesions. The lesions had their inception during the period of longitudinal growth. All of the lesions were in the long bones of the lower extremities. Jaffe and Lichtenstein found 1 lesion in the distal end of the ulna. All of the lesions were situated in the metaphysis or adjacent shaft usually eccentric and abutting on the cortex.

The symptoms are usually mild and consist of intermittent moderate pain often referred to the adjacent joint, and local tenderness.

Roentgenographically there is a limited area of reduced density in the metaphysis close to the epiphyseal disc which in later cases elongates and has a sclerotic margin, usually scalloped which gives the appearance of loculation. Later cases may show periosteal reaction.

The pathological appearance varies somewhat with the age and activity of the lesion. Fibrous connective tissue is the basis of the lesion in all stages. The recently formed focus shows a relatively cellular fibrous tissue with scattered multinucleated cells. The older lesions show fibrous tissue arranged in strands and whorls. Lymphoblasts are found scattered through the fibrous tissue. Lipoid filled macrophages are often present grouped or scattered. The lipoid deposition is evidence of chronicity. Concomitant epiphyseal disorders were observed in 14 cases. Spontaneous healing of the fibrous metaphyseal lesions was usual. In only a few cases was surgical eradication necessary for the relief of pain. The etiology of metaphyseal fibrous defects is obscure.

DAVID H. LEVINTHAL, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Robertson, L. M. and Barron J. N.: A Method of Treatment of Chronic Infective Osteitis. *J. Bone Surg.*, 1946, 28, 19.

The authors' treatment of chronic infective osteitis is based on the principle of extensive excision of all diseased tissues including skin, deep scars, and infected bone, and the replacement of soft tissue defects by muscle and skin flaps, and of bone defects by bone transplants.

This procedure may require two or three operative stages. In the first stage all of the diseased tissue is excised and a split skin graft is applied to the wound surface. In the second stage there is a plastic repair of the soft tissues. The original split skin graft is removed and the area is covered by a skin and subcutaneous flap, muscle being included where necessary. Stage three consists of repair of the bone graft. In some cases the second and third stages may be combined. An interval of 4 weeks is suggested between the first and second stages and one of at least 8 weeks between the second and third stages. In some cases the full diameter of the shaft of the bone may be involved.

Several diagrams, photographs, and roentgenographs are included in the original article. The details of the operative care in the three stages are discussed at length. A word of warning is given that this is not an undertaking to be lightly embarked upon by the operator.

RICHARD J. BROWETT JR., M.D.

Starr D. E.: Congenital Absence of the Radius. *J. Bone Surg.* 1945, 27, 578.

Three cases (involving four limbs) of congenital absence of the radius in its various aspects have been seen by the author.

The most interesting was a bilateral case with congenital absence of the radius, the thumb and the first metacarpal bones. The 3 other patients showed partial or complete absence of the radius and absence of some of the carpal bones. This deformity is disabling and very unsightly.

A three stage procedure is carried out whereby skeletal traction is applied, ulnar osteotomy is performed, and a fibular transplantation is carried out. The end result is particularly good in that it allows forearm rotation and wrist motion when part of the radius is present, and presents an extremely improved appearance.

RICHARD J. BROWETT JR., M.D.

Aitken D. M.: Late Results of Albee Fixation of Tuberculous of the Spine. *Proc. R. Soc. M., Lond.* 1945, 38, 685.

The author states that during the past 40 years the treatment of tuberculosis of the spine has passed through two phases and entered the third. The first phase consisted of fixation of the affected joints on a controlling splint until all pain and swelling had disappeared and the patient's condition was thriving. The second phase may be said to have begun about 1911 and was first applied in Robert Jones' practice, mainly to tuberculous disease of the spine. It consisted in the addition of a bone graft with the object of securing extra-articular fixation and bridging the diseased area to secure more complete fixation.

The third or present phase is based on the extraordinary results which followed successful employment of the Robertson-Lavalle technique which is briefly outlined. This procedure consists of drilling tuberculous foci which are believed to contain some defensive substance which cannot escape into the general circulation on account of the constriction of the issuing capillaries by the tough capsule about the focus. Drilling into the focus is supposed to let this mysterious substance out into the systemic circulation. Only young foci are drilled. These show on the x ray as faint blurred areas of decreased density.

Use of the procedure is said to be followed by marked improvement in the well-being of the patient. Pain usually disappears quickly and the degree of sepsis is lessened.

VERNON C. TURNER, M.D.

Dislocation of the knee joint is frequently associated with peroneal nerve injury and rupture of the popliteal artery. The latter complication occurred in 10 legs which had to be amputated because of subsequent gangrene.

Thirty-two patients were unconscious for periods varying from a momentary lapse to several days. They were thrown in a vertical direction up to 115 feet and horizontally up to 200 feet.

The first aid treatment of solid blast injuries is primarily devoted to saving life, i.e. the treatment of shock, splinting of the injured parts and evacuation to safer places for definitive medical care.

The final management of these patients follows along well known lines. It is noteworthy that skeletal fixation devices (Roger Andersen Stader) were found to delay union and cause osteomyelitis around the pin holes. Sailors who were in their bunks at the time of the explosion suffered the least injuries.

In conclusion 13 case histories are described in detail.

GEORGE L. REISS, M.D.

ORTHOPEDICS IN GENERAL

Bateman J. E.: A Universal Splint for Deformities of the Hand. *J. Bone Surg.* 1946 28: 169.

A splint is presented for the maintenance of adequate immobilization of the wrist and fingers deformed as a result of nerve injury. This apparatus prevents overstretching, eliminates undue pressure on devitalized tissues and avoids stiffness due to prolonged immobilization. Stiffness is avoided by re-

Fig. 1. The splint is applied in a paralysis of the median nerve, requiring finger and thumb correction. Note that the thumb may be pulled from the position of adduction.

moving the device twice daily, and actively and passively moving the immobilized parts. This process is made very simple by the construction of the universal splint.

The splint consists of a universal holder to which accessories consisting of steel arches (0.125 by 0.025 inch) twisted in a coil are attached. The spring arches are held on the holder by studs on fixed swivels.

The splint can be used as a posterior splint, as an anterior splint, and as a combination splint.

GEORGE L. REISS, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Gross, R. E.: Surgical Correction for Constriction of the Aorta. *Surgery* 1945 18 672.

Researches on dogs were carried out which indicated that the aorta could be completely transected and a normal vascular pathway reconstructed.

Two case reports are included in which the constricted area of the aorta was resected. In the first case the patient died of cardiac dilatation said to be due to the fact that the blood was allowed to re-enter the great vascular bed in the lower part of the body too rapidly. In the second case a 12 year old girl was studied and prepared for operation. The operation was carried out successfully in June 1945. The constricted area was resected and a satisfactory end-to-end anastomosis was completed. The patient made an uneventful recovery.

It was interesting to note that the blood pressure in the lower extremities came up to the normal level over a period of several days, while the hypertension in the upper extremities gradually decreased over a number of days. RICHARD J. BURKETT JR. M.D.

Paul, M.: The Surgical Treatment of Traumatic Aneurysms. *Br. J. Surg.* 1945 33 13.

The surgical treatment of large aneurysms is attended with difficulty and danger and the successful management of such cases demands a high degree of technical skill together with a proper appreciation of the problems of this branch of surgery. The author presents detailed reports of 8 cases. These indicate how problems have been met in individual instances that are not so common as to be within the experience of most surgeons.

A brief history of the surgical treatment of aneurysms is presented. The risk of gangrene of a limb following an operation in which the blood flow through the main artery has been obstructed by the operative procedure should be minimized as far as possible. If the arteries distal to the aneurysm exhibit a normal pulsation it is clear that most of the blood is still travelling through the main artery. In the traumatic cases the aneurysm is likely to be saccular and suitable for treatment by the restorative endoaneurysmorrhaphy method of Matas which carries almost no risk of interference with the main circulation through the limb. If on the other hand there is no pulse in the arteries distal to the aneurysm, it is clear that the circulation is being carried on mainly by collateral vessels and Matas advocates that the deficiency of the collateral circulation be estimated by the following method.

The limb is blanched by elevating it and by the application of a firm elastic bandage. The main artery is now compressed above the aneurysm. The elastic bandage is removed and the limb lowered. If the collateral circulation is efficient, there should

be a blush in the blanched limb within 3 minutes. If the collateral circulation is deficient, it can be improved by removing the sympathetic vasomotor control to the limb either by the operation of sympathectomy or more temporarily by the injection of the sympathetic field with novocain.

In conclusion the author notes that among the 8 cases of aneurysms described, the aneurysm was traumatic and saccular in 4 and the arteries distal to the aneurysm exhibited almost normal pulsation. In these cases the Matas operation for reconstructive endoaneurysmorrhaphy proved thoroughly practicable, the patient being cured by the operation.

In 3 cases the aneurysm was traumatic and fusiform. The arteries distal to the aneurysm showed no pulsation. Matas obliterative endoaneurysmorrhaphy served, however, to cure these patients of their aneurysms. In 1 case which unfortunately proved fatal, the aneurysm was due to the rupture of an arteriosclerotic calcified vessel. In this case the aneurysm had caused gangrene of the foot, which necessitated a disarticulation through the hip joint.

HAROLD F. THURMON, M.D.

Burton, R. W. and Collier, F. A.: Surgical Treatment of Long Standing Deep Phlebitis of the Leg. A Supplementary Report. *Surgery* 1945 18 663.

In the group of cases studied the long standing deep phlebitis of one or both lower extremities had its onset from 6 months to 30 years previously. Ligation of the femoral vein was carried out in individuals who had pain or disability resulting from chronic deep thrombophlebitis. The authors suggest that ligation of the femoral vein should not be carried out beyond the age of 55 years because of the advanced arterial diseases. Superficial varices were treated by ligation before the femoral vein ligation was carried out. The injection method of treatment of varicose veins was not used before, during, or after femoral ligation and none of the patients had received lumbar sympathetic block before during or after femoral vein ligation.

Of the 14 patients with ulceration, 6 have had complete healing of the ulcers for 1 year or longer. Others were healed for a shorter period of time. In 3 patients the areas are still unhealed. Reports indicate that there has been little improvement in the degree of swelling as compared with the preoperative status. Fatigue without exception continues to be a permanent symptom. When involvement was present above the level of the profunda femoris, vein ligation of the common femoral vein was carried out. It is believed that the level of vein ligation above or below the profunda femoris branch bears little relation to the degree or duration of postoperative edema, to the appearance of superficial varices postoperatively or to the end result.

The common iliac vein was ligated in 1 patient. Postoperative lumbar procaine injection produced little change in the patient's leg.

The inferior vena cava was ligated in 7 patients with a longstanding phlebitis of both lower extremities. The first patient upon whom a ligation of the vena cava was performed has now passed the twelve month period following it, and has no edema, although a prolonged trial without external supports has not been made. All the other patients in this group are still wearing supports. The outstanding end result in ligation of this type is the high incidence of healing of ulcers due to stasis. The most disappointing results have occurred in patients upon whom ligation was carried out when such ulceration was not present. The treatment has not been very satisfactory in this group.

RICHARD J. BERNETT, JR., M.D.

BLOOD; TRANSFUSION

Corelli, F.: *The Rh Factor the Cause of Fetal Erythroblastosis Hemolytic Disease of the Newborn and of Transfusion Reactions* (Il fattore Rh causa dell'eritroblastosi fetale, malattia emolitica del neonato e di reazioni da trasfusione). *Pediatrics* (n. ser.) 1945 51: 369.

This article is almost entirely a review of the American and English literature on the Rh factor which has already been ably reviewed. Its purpose is to acquaint such part of the Italian medical profession as is not already well acquainted with the subject—with the possibilities in the diagnosis and treatment of anemias, edemas, purpuras, and icteric conditions of pregnancy and infancy and with the explanation of many instances of abortion or premature delivery. Of course, many Italian doctors have been working in this field, for instance, Fontana has been transfusing with blood which is negative to the N factor.

The author himself finds an explanation of some of the mishaps in the past. For instance 1 of his recently observed patients who 3 years previously had received a number of transfusions without incident received another harmless transfusion incident to the development of a marked hypoplastic anemia. Thirteen days later she received another homogroup transfusion, which was succeeded an hour later by a typical severe reaction. Of course the mishap might be ascribed to the inadequacy of the crossmatching tests and even of the so-called biological test (an initial injection of 20 c.c. of the donor's blood with observation for 5 minutes thereafter). However, the author thinks that the patient had received blood in one of the previous transfusions which was positive for the Rh factor then in the first of the current two transfusions the blood was Rh negative and in the second it was Rh positive and this brought on the reaction. However the patient fortunately recovered.

Considerable space is given to the correspondence section of the *Journal of the American Medical Association* (1945 127: 1146) in which Darrow claims

that Rh positive blood should not be harmful to the erythroblastic infant. She postulates the correct methods of treatment for the condition, reserving perhaps for further study the question of transfusion with Rh positive blood and her opinions are accepted without reserve. The author also with apparent benefit has alkalinized the urine with bicarbonate of soda (4 gm. every 4 hours) and administered sodium lactate (Fox *J. Am. Med. Ass.* 1944 124: 127) for burn patients.

The author is now trying to build up a roster of Rh negative donors at the Uniti Hospital in Rome and intends to study further not only the question of the Rh factor but also the possibility of explaining the surprise reactions among the homogroups themselves in which the Rh factor does not always seem to be culpable. These reactions occur even in the O group and are possibly due to other as yet little noticed factors such as the factors M, N and P. He believes that other matters also should be included in these investigations such as the influence of the Rh factor in the unexplained occurrence of mental debility in children, as a high percentage of Rh positive infants delivered from Rh negative mothers has been found to be mentally deficient.

All of the aspects of this problem have been included under a broader conception which the author has designated as "Hemopathic Allergy." His book on this subject was published in 1944 by the publishing house of Pozzi in Rome.

JOHN W. BRENNAN, M.D.

LYMPH GLANDS AND LYMPHATIC VESSELS

Moreton, R. D.: *Lymphosarcoma with Primary Manifestations in the Gastrointestinal Tract. Report of 7 Cases Studied Roentgenologically*. *Texas State J. Med.* 1946 41: 458.

Lymphosarcoma is defined by Ewing as a true malignant neoplasm arising in lymphatic tissue from proliferation of atypical lymphoid cells. This occurs as (1) a localized or (2) a diffuse process. It is one of the larger groups of tumors referred to as malignant lymphoma or lymphoblastoma and should be classified under this general heading.

Because of the relative rarity of this condition the author thought it was advantageous to present a brief review of the pathological and roentgenographic findings as well as to present 7 cases of lymphosarcoma which manifested themselves as gastrointestinal lesions and were studied roentgenographically.

Two types of this tumor are recognized: the small cell lymphosarcoma or malignant lymphocytoma, and the large cell or reticulum cell lymphosarcoma. Some authorities believe the distinction between the two types is important from both therapeutic and prognostic standpoints. In the gastrointestinal tract the growth originates in the submucosa and invades in each direction involving on one hand the

mucosa, and on the other the muscularis of the bowel.

In summarizing the author notes that the term "tumefactive lesion" should be a useful one in the roentgenological field just as in gross pathological diagnosis. This term is used as a general one and does not define a specific etiologic or histological process, and is therefore used before the more refined methods of diagnosis are employed.

Radiologists are among the first to believe that roentgenological examination can be made to establish the presence of any tumefactive lesion in the gastrointestinal tract at least as early in the anatomic development of the lesion as the latter is able to cause symptoms and be manifested by clinical signs. A neoplastic lesion may be distinguished from a non-neoplastic lesion with about the same accuracy after the examination of the gross specimen. Surgical exploration has substantiated these beliefs to the extent that such roentgenological capabilities are well recognized.

Due to the rarity of lymphosarcoma as compared to carcinoma as well as the similarity of lymphosarcoma in the gastrointestinal tract to that of carcinoma in the same location, there is the tendency to report all of these lesions as carcinomas rather than tumefactive lesions or malignant neoplasms at the particular site noted.

In this condition the roentgenological findings are not sufficiently characteristic to allow a specific

diagnosis of lymphosarcoma of the gastrointestinal tract and for the reasons which have been stated carcinoma is the diagnosis that is most frequently made.

In conclusion, the author states that 7 new cases of lymphosarcoma with primary manifestation in the gastrointestinal tract have been presented. The series included 5 women and 2 men. The youngest patient was 51 years of age the oldest, 74. No distinguishing features of lymphosarcoma were found either in the history or on roentgenological examination. The 7 lesions viewed roentgenologically had an appearance indistinguishable from that of carcinoma.

All patients were subjected to an exploratory operation, the diagnosis being made from biopsies. Five of them were subjected to postoperative roentgen therapy as noted in the case reports. Five of the 7 patients have died, one, 10 days postoperatively of bronchopneumonia and the others, 7½ months, 20 months, 16 months, and 2 months, respectively, after first being seen at the clinic, apparently from the lymphosarcoma.

Two patients with involvement of the stomach were last seen at the clinic 34 and 36 months after their first admission. They showed no evidence of recurrence. One of these patients had been treated by resection and postoperative irradiation the other received irradiation alone.

HAROLD F. TAYLOR, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Smith, B. Cornell C. and Neill C. L.: Principles
in Early Reconstructive Surgery of Severe
Thermal Burns of the Hands *Brit. J. Surg.*,
1945 33 155

Regulations directing the proper use of protective
fire resisting apparel will reduce burn hazards in
military operations. Characteristic wartime burns
of the hand involve the tissue over the dorsum of the
hand and fingers and have a tendency to encircle the
wrist.

Deformity and disability resulting from thermal
burns of the hands may be reduced by early manage-
ment. The initial treatment is directed toward the
prevention of infection and the restoration of func-
tion. However infection and exposed tendons and
bones do not contraindicate early grafting. Radical
excision of slough granulation tissue and poorly
developed epithelium prepares the recipient surface
for a split thickness graft which is sutured in place
under the tension of normal skin.

Postoperatively dressings and splints are removed
on the fifth day. Rehabilitation exercises are ob-
served until maximum functional activity is ob-
tained.

Levenson S. M. and Lund, C. C.: Dermatomic Skin
Grafts for Burns in Patients Prepared with Dry
Dressings and with and without Penicillin
N. England J. M. 1945 33 607

Up to the time of the work presented in this re-
port, the results of skin grafting at the Boston City
Hospital were similar to those reported by Hirsch
et al. namely that in about one-third of the cases
there was less than 75 per cent take and in many of
the cases the failure was 100 per cent. It was there-
fore decided to try the use of penicillin given pre-
operatively.

Twenty-eight dermatomic grafts were done on 19
patients with granulating third-degree burns. One-
half of the patients received parenteral penicillin
treatment before and after grafting and the other
half received no penicillin.

In other respects the techniques used in the two
groups were identical. Before and after grafting dry
sterile pressure dressings were applied with adequate
splinting. The condition of the patients, the extent
and site of the burns, and the extent of the graft
were similar in the two groups.

All granulating areas were locally infected, but
there were no cases of spreading infection.
The hemolytic staphylococcus aureus, the proteus
vulgaris, and the pseudomonas aeruginosa were the
predominant organisms.
Penicillin had no effect on the bacterial flora or
the appearance of the wounds.

The results obtained in both of the groups were
excellent.
Simple dry sterile pressure dressings, infrequently
changed are recommended before and after skin
grafting.

It appears that the improvement in the results of
skin grafting that was coincident with the start of
this hospital was not due to penicillin since the results
of this study were not due to penicillin were
essentially the same as those in the patients who did
not receive penicillin. It should be emphasized however that
the results in the control cases were such that the
takes in the penicillin treated series would have had
to be essentially perfect in all cases to show a sig-
nificant improvement. There was no change in the
cultures from or in the appearance of penicillin treat-
ing wounds during the period of penicillin treat-
ment. It should be stressed however that there
were no cases of septicemia or cellulitis, the infection
being confined to local areas.

DANIEL H. LEVINTHAL, M.D.

Schmidt, E. R. and Hibma, O. V. Mortality after
Operation *West. J. Surg.* 1945 53 427

The authors have reviewed all deaths (138) follow-
ing operations done at the Wisconsin General Hos-
pital Madison in the year 1942. Classification of
these cases on the basis of evaluation as to the risk
of the given procedure shows that other factors such
as the type and amount of surgery play a greater
role.

Although the majority of deaths occurred in
the fourth, fifth and sixth decades it was believed
that more operations are done in these age groups
and that the mortality is actually highest in the very
young and the very old.

A review of the deaths occurring from 1938 to
1942, classified according to the recommendations of
the American Society of Anesthetists, shows a very
direct correlation the mortality varying from 0.085
per cent for those in the best physical state to 57.5
per cent for those practically moribund before
operation.

Seven deaths in the operating room are reported
with brief abstracts. The author points out that if
one is more interested in relieving the sufferings of
the patients than in the mortality rate the deaths are
unavoidable. More than half of the 138 patients
died after the third postoperative day.

Three conditions accounted for 45 per cent of the
deaths: pneumonia (19.5%) and cardiac failure (14.8%)
and failure (14.8%).

The authors emphasize that evaluation as to risk
is important that risk varies with the experience and
the clinical judgment and acumen of the surgeon and
anesthetist that routine orders are dangerous and

that close attention to particular systems without neglect of the patient's general condition is essential.
THOMAS C. DOUGLASS, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Weinstein L. and Wesselhoof, C.: Penicillin in the Treatment of Tetanus. *England J M* 1945 33 682

Two cases of severe tetanus are reported in which recovery followed treatment with large amounts of antitoxin, surgical excision of the wounds and administration of large doses of penicillin.

Bacteriologic studies revealed that clostridium tetani could no longer be isolated from the wounds in these patients 24 hours after the first administration of penicillin. The already demonstrated antibiotic influence of penicillin on this organism in vitro therefore, appears to be confirmed in vivo.

The use of penicillin in tetanus appears to be most valuable in cases in which multiple lesions not all of which can be removed by surgical means, are present or in which no focus of infection is detectable. This antibiotic agent is not intended to replace the administration of antitoxin, excision of wounds, adequate sedation, and maintenance of a normal state of nutrition and hydration, but appears to be a highly important adjuvant to these other therapeutic measures.

McAdam, I W J: Penicillin Treatment of Acute Hematogenous Osteomyelitis. *Brit. J Surg* 1945 33 167

The lifesaving properties of penicillin are discussed, and its limitations in local infection and bone necrosis are emphasized in conjunction with 40 patients in whom penicillin treatment was used. The long bones were affected in 32 of the patients. The usual daily dose of penicillin was 100,000 units. Larger doses were used when indicated. Quite a wide variation in the serum level of penicillin was found.

Intramedullary injections of the penicillin produced a higher concentration in the pus. The intramedullary method is recommended when the infected metaphysis is intracapsular and there is an almost inevitable septic arthritis. It would appear from the results reported here that a route for the passage of penicillin from the metaphysical focus to the infected joint cavity is open. The introduction of a needle into the medulla of an infected bone serves several purposes: it allows the aspiration of a subperiosteal abscess; it relieves intramedullary tension; and it allows a bacteriological diagnosis to be made from the pus. In addition, it is used to administer the penicillin.

The length of time that organisms are found in the medullary cavity is very important in order to decide the duration of treatment. Among 18 patients, the average time for staphylococcal infections to be cleared up was 14 days, and the treatment was continued until three successive daily specimens of

pus proved to be sterile. The temperature chart and leucocyte count were not found to be reliable as guides to the severity of the local infection. Of 40 patients 31 had a generalized infection, 10 had metastatic foci, and 20 had positive blood cultures.

A large table is given in the original article, showing the details of treatment in 40 cases of acute hematogenous osteomyelitis. Among 32 patients with acute infections of the long bones treated with penicillin, 5 had operative treatment and the remaining 27 were treated conservatively. In 10 of the 40 patients septic arthritis occurred. This complication is most effectively treated by the aspiration of joint cavity every second day. Among 22 of the 32 patients who had infections of the long bones, 2 have poor function because of destruction of a joint; 1 patient developed a pathological fracture and 2 patients have discharging sinuses. In the remaining 17 patients, good function has resulted.

Penicillin treatment sterilizes bone in an average of 14 days. Before sterilization, however bone damage has occurred, even though it is not evident roentgenographically. Immobilization would appear to be advisable until there is roentgenographic evidence of recalcification.

In this series of 40 patients 19 had a staphylococcal septicemia, 9 had metastatic lesions, and 10 had a septic arthritis there was 1 death.

ROBERT J. BENNETT JR., M.D.

Kirby W B M., Leifer W., Martin, S. P., Rammeikamp, C. H., and Kinman J M: Penicillin in Oil. *J Am M Ass* 1945 129 940

Penicillin beeswax-peanut oil mixtures provide an effective and safe means of prolonging the action of penicillin in the body. Studies were made of the absorption and excretion of penicillin following intramuscular and subcutaneous injections of 300,000 units of penicillin in a 4.8 per cent beeswax in oil mixture. A single injection was administered to 51 patients with acute gonococcal urethritis and 35 received 8 daily injections, a total of 2,400,000 units in 8 days.

Calcium penicillin was used rather than the sodium salt because it was less hygroscopic, although there was thought to be no significant difference in the duration of the blood levels or in the clinical results because of the particular salt used. Penicillin was suspended in a 4.8 per cent beeswax in oil preparation. Intramuscular injections were made into the gluteal or deltoid muscles, and subcutaneous injections, into the subcutaneous tissues overlying the insertion of the deltoid muscle. The variability of absorption and excretion was striking, an important factor being the location of the injected material in relation to the muscle tissue and fascial planes, while the activity of the patient was apparently of minor consequence. It was concluded that there must be a continuous absorption from the muscle of a large amount of penicillin to insure ab-

sorption of about 2 500 units per hour. Slower more uniform absorption was obtained with subcutaneous injections because there are fewer and smaller blood vessels in the subcutaneous regions than in the deep muscle tissues therefore this route was considered superior although it was used in only 25 cases in this series.

Penicillin levels in the blood and in the urine were obtained in the 89 cases. The blood levels were determined by the Kirby Rantz modification of the Rammelkamp serial dilution technique (which detected as little as 0.04 units per cubic centimeter) and specimens were taken $\frac{1}{2}$, 1, 4, 8, 12, 16, 20, 24, and 28 hours after the injection. In 69 per cent of the 54 patients with gonococcal urethritis the blood levels were present for no longer than 12 hours and in about half of the 31 per cent in whom the levels were present for from 16 to 28 hours. Irregularity of absorption during the second 12 hours was noted. In only 7 per cent of the 33 luteic patients assayable levels of penicillin were present 24 hours after each injection. No cumulative effect of penicillin was noted. In both groups of patients urine was collected in 12 hour periods for from 48 to 72 hours and follow-up clinical observations were performed for a minimum of 31 days. The excretion of penicillin was found to decline rapidly after the first 12 hours but small amounts could be detected for 72 hours or more. The urinary excretion confirmed the evidence of superiority of the subcutaneous over the intramuscular route of injection.

In the one third of the patients who received subcutaneous injections it was observed that the absorption was more uniform and the levels were more prolonged in approximately two-thirds of these patients penicillin was present in the blood in detectable quantities for 24 hours or more.

From the preliminary clinical results it is concluded that, although larger amounts of penicillin are required than with penicillin in saline solution, penicillin-beeswax-peanut oil mixtures provide an effective and apparently safe method of prolonging the action of penicillin in the body. It is further concluded that an injection of the penicillin in oil mixture (300,000 units) should be made twice a day for treatment of infections in which it is desirable to maintain a therapeutic concentration of penicillin throughout the duration of treatment.

Soreness at the site of injection which persisted for 9 or 10 days was the only significant manifestation of the penicillin in oil injections (3 of the luteic cases developed a generalized urticaria) and this was less severe in the subcutaneous administration.

PHILIP B. CHART, M.D.

ANESTHESIA

Pleasance, R. E. Intravenous Anesthesia in the Tropics. *Current Res Anesth.* 1945 24 831.

This article is based upon experiences at a Base Hospital, and covers a period of 2½ years with intravenous anesthesia mainly pentothal sodium.

During this period 3 994 of 7 952 anesthetics, approximately 50 per cent, were intravenous anesthetics of some form. There were no fatalities in this series and no definite postoperative pulmonary complications. The operative cases varied considerably and included most types of minor surgery and diagnostic procedures, as well as maxillofacial, plastic, orthopedic, and extensive surgery of the cranial vault, chest, and abdomen. Pentothal alone was used when possible but the more extensive procedures were performed under a combination of pentothal and some other form of anesthesia, preferably gas and oxygen.

The author lists the following types of cases as suitable for intravenous anesthesia.

Patients who desire to avoid unpleasant inhalation agents.

Patients who resist other forms of anesthesia.

Patients who are unable to tolerate a mask over the face.

Patients who have had little or no premedication.

Patients who require a supplement to spinal anesthesia.

Patients who are subjected to minor operations manipulations or examinations under anesthesia.

Patients who are subjected to selected major operations.

Patients who require an antidote to the toxic effect of local anesthetics.

Patients who are having convulsions from drug poisoning either or tetanus.

Patients who require sigmoidoscopic or cystoscopic examinations or application of the diathermic cautery.

The tendency toward laryngeal spasm makes the use of pentothal for bronchoscopy hazardous unless an expert in the arts of both anesthesia and bronchoscopy administers the pentothal. Lundy's method of reinforcing the preliminary infection after a few minutes of waiting and proceeding to a deep plane is advocated.

The following patients are not suitable for intravenous anesthesia.

Children under 7 years of age.

Patients with severe liver and kidney disease.

Patients with suppuration in the neighborhood of the neck.

Patients with cystitis and latent pyelitis.

Possibly patients with asthma and those who have been treated with preparations of sulfanilamide, those with dyspnea from any cause, with severe anemia, cachexia and dehydration with cardiac decompensation, with hypotension, or with varicosities are also unsuitable for intravenous anesthesia.

In this extensive series, the author noted some complications such as venous thromboses, severe headache, unusual urticarial-like eruptions, vomiting, exacerbation of latent malaria, priapism, jaundice, and intra-arterial infections eventuating in the loss of the extremity.

Since barbiturates are broken down in the liver and excreted by the kidneys great care must be

exercised in the use of pentothal in a tropical climate, where liver disease or deficiency is comparatively common. The fall in blood pressure and depression in respiration depend upon the rapidity with which the anesthetic agent is injected. The four stages of anesthesia discussed are light narcosis, the "stage of inebriation anesthesia, and premortem."

Induction, as well as recovery is quiet, but occasionally the patient is irrational, noisy and hyperactive. Whenever possible, the solution (2.5%) should be freshly prepared at least 10 or 15 minutes before injection. Preoperatively the patient should be prepared as for a general anesthetic, and if the procedure requires a prolonged anesthesia, morphine (gr 3/4) and atropine (gr 1/100-1/150) should be given. The following techniques of administration are used (a) the single dose (b) the intermittent dose and (c) the continuous dose. These techniques were dependent on whether the case was (1) a simple surgical procedure, (2) a general surgical procedure requiring prolonged anesthesia, (3) a cerebral case, (4) a case of maxillofacial surgery or (5) a case of thoracic surgery. Postoperatively routine use is made of one of the detoxicant drugs—coramine, phreparol, or picrotoxin, and the patient is carefully watched until the return of reflexes or even consciousness. The author judiciously concludes, "The ease of its administration may constitute the greatest danger of pentothal."

DAVID H. LYNN M.D.

Edwards, G: Trichloromethyl Alcohol (Avertin, Bromethol) *Proc. R. Soc. M. Lond.* 1945 39 71

The author describes the first case narcotized by avertin in England as well as additional experiments with the drug up to the present time. It is now being administered routinely.

This drug has had widespread popularity from its initial introduction into England in 1927. In 1936 50 per cent of the hospital patients and 65 per cent of the patients in nursing homes were given avertin. However its popularity has waned since that time during the last 12 months less than 5 per cent of the

hospital cases and less than 10 per cent of the private patients have received this drug. A 1/10 gm. per kilogram dose has been used from the start. The original 3 per cent solution used has been changed to a 2½ per cent solution. The Congo red test was used to determine traces of hydrobromic acid. Rectal plugs and postoperative washouts were used at first but were soon discarded as worthless. It was soon learned that avertin should be given as a basal anesthetic only total anesthesia with the drug was found to be dangerous.

Avertinized patients retain an active cough reflex. Coramine gives an effective counteraction to an overdose. Although avertin is unlikely to damage a healthy liver it should be avoided if there is any suspicion of impaired hepatic function. It has little effect on renal function and nitrogen excretion. It is not recommended for chest surgery because prolonged basal narcosis is found to be a contributing factor in postoperative chest complications. There is no contraindication to its use for throat surgery. It is indicated in hyperthyroid patients and those patients who prefer to be asleep before going to surgery. It is contraindicated in inflammations or lesions of the rectum or large bowel, in operations in the region of the rectum, and in any condition which produces a definite deviation from the physical normal, such as fever anemia, obesity cardiac or respiratory affections and renal or hepatic lesions.

The author's present routine consists of administering an enema from 6 to 12 hours before surgery and giving atropine (gr 1/100) 10 minutes following the avertin injection. The avertin dose is 1/10 for a gram per kilogram with a maximum of 8 gm. Trichloromethyl alcohol was used in a group of 18 cases. This drug was found to be more hypnotic and to cause less respiratory depression than avertin. It caused excitement both during the onset of narcosis and during recovery and the eighteenth case presented cardiac failure early during the onset of narcosis. For this reason the use of trichloromethyl alcohol was discontinued.

MARY KARP M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Packard, C. Roentgen Radiations In Biological Research. *Radiology* 1945 45 532

This article summarizes the study of the effect of the roentgen rays on living cells since Roentgen's discovery in 1895 and the use to which these effects have been put in biological research. It was discovered early that x rays were of little use as a bactericidal agent, but that large doses resulted in the coagulation of plant and animal cell protoplasm. There was early recognition of the sterilizing effect of the x rays on animals and both radium and roentgen rays have been of use in analyzing the role played by the cytoplasmic portion of the sperm and egg since it has been found that the nuclei of gametes can be injured in varying degrees without preventing cleavage of the egg.

Three types of chromosome change following irradiation have proved important cytogenetically by causing an increase in the number of mutations and chromosomal aberrations over the rate found in nature, and apparently giving rise to the same alterations in the hereditary material as in the spontaneous cases. x rays furnish a valuable means of study of such phenomena. The first of these small changes consists of the increased stickiness of pairs of chromosomes which causes some of them to stick together instead of separating during the maturation process with resultant hereditary changes in the offspring. Radiation may increase the frequency of this phenomenon over that found in the offspring of nonirradiated parents by as much as 20 times. The second of these changes consists in the sticking together of certain portions of the chromosomes and their subsequent breaking apart under the pull of spindle fibers with subsequent reattachment of fragments either to the same chromosome in their original orientation or in reverse position or to the broken ends of other chromosomes. Precise determination of the chromosomes involved and the fate of their parts has been achieved in careful experiments. The third effect is a change in the gene itself which greatly increases the mutation rate (Muller in 1927 working with *Drosophila*) this increase is proportional to the amount of energy absorbed.

Sensitivity to radiation changes rapidly during mitosis, but whether prophase, metaphase or telophase is the most vulnerable period is still in dispute. It was demonstrated by Bergonie and Tribondeau in 1906 that the sensitivity of cells in general varies with their reproductive capacity and inversely with their degree of differentiation, and it has been established that during the development of an organism there is a progressive loss of sensitivity. Although decrease in sensitivity is synchronous with decrease in growth velocity experiments which

induce increase in the normal growth rate have not produced a comparable increase in radiation effect. It appears that when cell division and metabolism are at a minimum as during chilling cells have a better opportunity to recover from their injury but Henshaw and Francis working with wheat seeds found no quantitative relation between susceptibility and water absorption, oxygen consumption and mitosis although sensitivity rises when water is absorbed and growth commences.

There is general agreement that the primary effect of irradiation on the tissues is an ionization, resulting in transformation of complex molecules to simpler ones but the precise point of primary attack and the pattern of chain reactions which may be precipitated has yet to be worked out. x rays have been repeatedly shown to have no direct effect on oxygen consumption but work by Crabtree and Gray indicates that they have an effect on glycolysis and work by Dale that they inactivate dilute carboxypeptidase while Sparrow states that perhaps the sensitivity to x rays may be correlated with the nucleic acid metabolism.

In 1904 Koernicke demonstrated the ability of organisms to recover from x ray injury but it was not until 1932 that Henshaw offered quantitative data in proof of the generally accepted principle that when x ray intensity is low the rate of repair is sufficient to balance the rate of injury. He found that when arabidopsis eggs are irradiated and then fertilized, the onset of division is delayed the delay being an exponential function of the time interval between the end of exposure and the moment of fertilization and the period of recovery apparently being limited to the quiescent interval between irradiation and fertilization.

LILIAN DONALDSON, M.D.

Sinberg, S.E., and Burman, M. S.: Roentgenologic Visualization of the Fractured Temporal Styloid Process. *Radiology* 1945 45 599.

The roentgen visualization of the temporal styloid process is often difficult. The lower part of the bone may be seen in posteroanterior roentgenograms made for the demonstration of the maxillary sinuses, in the open mouth view of the edentulous patient, and in the lateral view of the nasopharynx and neck, but the entire bone is shown rarely.

The authors became interested in the roentgen visualization of the styloid process in connection with a rather unusual case which is described in the text and illustrated with their respective roentgenograms.

A technique developed from that of Kaplan was found to be of definite value. It is given as follows:

For visualization of the right styloid process, the patient is seated in the right oblique position (about 15 degrees) with head bent to the right at an angle of

about 10 degrees. The head is extended about 10 degrees to bring the mandible out of the line of the styloid. The cassette is placed upon the patient's right shoulder and held firmly against the side of the neck and head by his right hand. The x-ray tube is set from 30 to 35 cm. to the left of the patient's knees. The tube is then tilted upward about 45 degrees and backward about 30 degrees, so that the central ray enters the left side of the neck in an oblique and upward direction from 3 to 4 cm. below the angle of the mandible.

By making use of this technique the authors were able to demonstrate a fracture of the temporal styloid process in both cases. T. LECURU, M.D.

Renander, A.: Roentgenologically Examined Cases of Cancer of the Thymus Gland (Röntgenologisk undersökt Fall von Cancer thymus). *Acta radiol.*, Stockholm, 1945, 26: 197.

The consensus of roentgenologists is that roentgenograms of malignant tumors of the thymus gland are not characteristic enough to allow a definite diagnosis. However, Lenk called attention to certain features which permit a correct diagnosis in a large percentage of cases. The author of this article describes a case of cancer of the thymus gland in which the picture differed in certain respects from that considered as characteristic for malignant tumor of the thymus gland by Lenk.

According to the prevailing opinion the medullary substance of the thymus gland is of endothelial origin and therefore belongs to the epithelial structures while the cortical substance is formed mostly by cells deriving from lymphocytes. It follows that malignant medullary tumors of the thymus gland belong to the group of lymphosarcomas. This classification must be kept in mind when x-ray irradiation is employed for diagnostic purposes because a carcinoma while a sarcoma yields to the therapy promptly resembling the lymphosarcoma of the mediastinal glands in this respect. In this manner a carcinoma can be differentiated from a lymphosarcoma.

The clinical picture is dominated by pressure symptoms. Frequently signs of congestion in the region of the superior vena cava are noticed later on dyspnea, cachexia and metastases develop.

According to Lenk, malignant tumors of the thymus gland located in the anterior mediastinum form more or less symmetrical tumefactions which as a rule reach the base of the heart. In contradistinction to glandular tumors located in the anterior mediastinum the upper border of a thymus tumor does not reach the "jugulum." As a rule, a thymus tumor has a rounded shape with polycyclic margins, while glandular tumors form relatively short arches, while arch formations are characteristic for thymus tumors. Contrary to glandular tumors the transverse diameter of thymus tumors exceeds that of the longitudinal diameter this being due to the growth of

thymus tumors within a preformed capsule. In roentgenograms the thymus tumor forms a sharp outline unless the tumor mass penetrates the capsule and infiltrates the adjacent pulmonary tissues. A thymus tumor usually causes a displacement of the adjoining organs. Dermoid cysts, accessory spleen, and aneurysms are characterized by an asymmetric shape.

In a case of malignant thymus tumor in a 75 year old man observed by the author, the type of the mediastinal tumor could not be determined roentgenologically. A percutis of the phrenic nerve and an enlarged cervical gland suggested malignancy. The diagnosis was supported by the asymmetrical shape and an extension of the mediastinal tumor into the right cervical region. A complete regression of the enlarged cervical gland under the influence of x-ray treatment supported the diagnosis of malignancy of a lymph gland. On the other hand the outlines of the tumor in the roentgenograms were sharp long polycyclic arches were noticed, and the transverse diameter of the shadow was slightly longer than the longitudinal diameter. The microscopic examination of the tumor revealed a cancer of the thymus gland. JOSEPH K. NARAY, M.D.

Duane, L., Hermon, R., and Dagnall, D. J. T.: Pneumococci in Radiator and Boiler Flashes. *Brit. J. Radiol.* 1945 18: 377.

Chest roentgenographs of 13 boiler fitters and radiator fitters showed signs of pneumococci in 10. Only 2 had disabling complaints and the chest films of 1 of these 3 men were essentially negative. The authors attribute the roentgenographic findings to inhalation of dust consisting of sand (from the casting molds) iron, and oil. The exposures ranged from 9 to 36 years.

An analysis of 3 dust specimens, which were obtained by different collecting methods, showed that the content of iron ranged up to 6.5 per cent. The main constituent was silica. Its solubility depended on the size of the particles. The amount of soluble silica did not exceed 0.45 per cent. The average size of the particles was 5 microns in the unfiltered specimen. GERHART S. SCHWARTZ, M.D.

Wilson, A. K.: Roentgen Examination in Congenital Intestinal Obstructive Defects in Infants. *Am. J. Roentol.* 1945 54: 498.

The author presents 3 cases of congenital obstructive anomalies of the intestinal tract in newborn infants, and describes the roentgen techniques used in ascertaining the point of obstruction. For cases of imperforate anus and rectal atresia he uses the method described by Wangenstein and Rice in 1930 whereby gas in the large intestine is used to delineate the blind end of the rectal pouch by suspending the infant head down and placing a radiopaque object in the anal dimple. This demonstrates the extent of separation between the blind end of the rectum and the perineum to aid the surgeon in determining whether a perineal approach is feasible. In

Fig. 1 Case 1. Anteroposterior and lateral views made (a) immediately (b) 5 minutes after and (c) 10 minutes after the infant was suspended head down. Note gradually increasing ascent of gas in rectal pouch, and that there is greater clarity of detail and less risk of erroneous measurement in the lateral projection. The tip of the thermometer is in contact with the anal dimple.

Fig. 3 Case 3. The findings in (a) reproduced from a roentgenogram made 10 minutes after the infant was suspended head down, show evidence suggestive of high rectal imperforation. This was disproved by insufflation of air (b)

and the injection of iodized oil (c). The partially calcified enterocyst is seen in (c) and (d) in close proximity to the mobile proximal end of the colon.

cases showing an anal pouch, injection of opaque medium is recommended for an accurate estimate of the depth of tissue between the anal membrane or perineal surface and the blind end of the rectal pouch.

In one of the cases presented 5 per cent lactose was given by mouth some hours before examination in order to increase gas formation in the bowel in the newborn. Roentgenograms were then made at least 5 and preferably 10 minutes after the infant was inverted in both the anteroposterior and the lateral projections. It was found that if films were made immediately after inversion the gas might not have reached the distalmost portion of the rectal pouch whereas the gas localization after 10 minutes corresponded well with subsequent surgical findings. The lateral projection was found of greater value in estimating the thickness of the tissue between the rectal pouch and the perineal skin surface since the pelvic curve of the intestine foreshortens the distance between these points in the anteroposterior view. The latter projection may be of value however in demonstrating possible deviation to the left or right of the terminal end of the rectum.

The first case was that of a premature male infant, with no anal orifice but with an anal dimple. It was given 35 ounces of 5 per cent lactose by mouth approximately 12, 15 and 18 hours after birth, and at 27 hours was suspended head down with a thermometer tip in apposition to the anal dimple. Anteroposterior and lateral films were taken immediately and 5 minutes and 10 minutes after suspension, and the lateral views showed the distance between the gas-distended, closed end of the rectum and the tip of the thermometer to be respectively 5 cm, 1.5 cm., and 1 cm. (Fig. 1). Confirmation of the accuracy of the 10 minute film was obtained an hour later when incision was made through the anal dimple and the blind pouch was encountered 1 cm. above the cutaneous margin.

The second case was similar to the first.

The third case was that of a premature female infant who developed persistent projectile vomiting about 2 hours after birth. The first films (Fig. 2) made 18 hours after birth by the method described, tended to support the clinical impression of high rectal atresia as there was considerable distance between the tip of the rectal catheter and the collection of rectal gas. The insufflation of air and injection of 15 c.c. of iodized oil, however, demonstrated free passage up the colon as far as the transverse portion which was displaced to the left by a large movable partially calcified cystic mass. In spite of ileostomy the infant died 60 hours after birth. Autopsy showed a large enterocyst joined to the terminal ileum by a fibrous strand and to the mid ileum by an almost atretic loop while the terminal ileum ended blindly a few centimeters from the colon.

Cases 2 and 3 were the only cases of imperforate anus or intestinal atresia found among 9,474 living babies born in the Hospital of St. Vincent de Paul Norfolk, Va. between 1923 and 1944.

LESLIE DONALDSON M.D.

Isaac, F. I. Roentgen Findings in Amebic Disease of the Liver. *Radiology* 1945 45 581.

The author calls attention to amebic disease of the liver manifested first as a diffuse hepatitis and progressing in some instances to the formation of solitary or multiple liver abscesses, as the most common complication of amebic dysentery and reports that of the 222 cases of such dysentery reviewed at an Army hospital overseas, 32 (14%) were diagnosed as presenting liver involvement.

The onset of this complication is usually insidious with only anorexia, malaise, and vague epigastric distress with the result that the patient may not appear for diagnosis until several months after an initial attack of diarrhea, and then usually with only low grade fever, moderate leucocytosis, an elevated sedimentation rate and tenderness over the liver without any frank pathognomonic signs on physical examination. For this reason the author believes the associated roentgen changes, if present, may be of considerable help in suggesting or clinching the diagnosis.

Of the 32 cases diagnosed as amebic hepatitis 22 were examined roentgenologically, of these, 10 (45%) showed elevation of the right leaf of the diaphragm in the chest films, and fluoroscopic movement of the diaphragm was reduced or absent. In regions where amebic dysentery is prevalent, the author regards these roentgen findings pathognomonic of amebic liver disease. Secondary compression of markings in the base of the right lung frequently accompanied the diaphragmatic elevation and occasionally there was a little pulmonary infiltration. In a few instances minimal right costophrenic pleuritis and effusion were also encountered which the author believes was due to rupture of a liver abscess into the pleural cavity. Prone abdominal films were not always helpful, but in some cases they did show a downward extension of the inferior hepatic border as related to the costal margin.

Following a course of emetine therapy these roentgen signs disappeared but more slowly than the symptoms. In only a very small percentage of cases did amebic liver disease require aspiration.

LESLIE DONALDSON M.D.

Brooke, H. H. W., MacKenzie, W. C., and Smith, J. R.: Pneumoroentgenography with Oxygen in the Diagnosis of Internal Derangements of the Knee Joint. *Am. J. Roentg.* 1945, 54 462.

The authors used oxygen pneumoroentgenography for the diagnosis of internal derangements of the knee joint whenever the clinical evaluation remained inconclusive and the routine roentgen examination failed to help although the symptoms strongly suggested some sort of disability.

A total of 25 cases were examined of which 18 showed positive findings. Ten cases came to operation and in all but 1 the roentgen findings were confirmed. The failure in the tenth case was attributed to insufficient removal of the synovial fluid and in complete filling of the joint cavity with oxygen.

The authors give in detail the anatomic and surgical considerations. The procedure must be done in the operating room under aseptic conditions. From 100 to 140 c.c. is the optimum amount of oxygen necessary for good filling. Collodion is applied to the needle puncture site and then the patient is taken to the roentgen department on a stretcher. Roentgenograms are made in standard positions. The use of the curved cassette holder and multiple stereo projections are however of definite value.

In the interpretation of the abnormal pneumo-roentgenogram of the knee joint the following points were found to have diagnostic significance: (1) roughening and narrowing of the cartilage surfaces either of the articular surface coverings or of the semilunar cartilages; (2) uninterrupted gas columns along the inner aspect of the collateral ligaments of the joint where capsular structure should be firmly attached to the periphery of the menisci; (3) increased density in the intercondylar or nonarticular region with a corresponding lack of density in the lateral or medial region of the joint; (4) separation of the meniscus shadow from the contiguous bone structures; (5) calcified and more especially non calcified loose or semiloose bodies (joint mice); (6) narrowing of the joint space and (7) exostosis or churning of the articular surfaces. The last three findings can also be demonstrated in the routine roentgenograms of the knee.

The conclusion is reached that the method is a useful adjunct in well selected cases. Under aseptic surgical conditions it carries little risk of complications.

T. LEUCOTTA, M.D.

Coolidge, W. D. and Charlton E. E.: Roentgen Ray Tubes. *Radiology* 1945 45 449

The authors describe the technological development of x ray tubes from the simple gas discharge tube first used by Roentgen in which the glass wall of the tube functioned haphazardly as the x ray emitting target under bombardment by electrons to the one hundred million volt circular induction electron accelerator tube, which promises to become not only a widely used instrument in medicine and industry but also a source of unpredictable scientific information.

There are essentially 3 groups of x ray tubes: 1. Gas filled tubes, most of which operate with a cold cathode. They are antiquated mainly because of their instability and the impossibility of controlling the current passing through them and of choosing the voltage applicable to them independently from current and gas pressure.

2. High vacuum tubes with a cold cathode (so-called field current tubes) which did not gain acceptance for similar reasons.

3. High vacuum tubes with a hot cathode. This type of tube is the only kind used extensively today. It was developed by one of the two authors (Coolidge) whose name it bears. Encouraged by the work of Langmuir he developed a hot cathode which con-

sisted of an electrically heated tungsten filament whereas Lilienfeld tried to solve this problem by introducing an auxiliary hot cathode which produced electrons in a separate ignition chamber.

Coolidge tubes have now been developed to cover a wide range of usefulness. They vary in size from that of an oil immersed dental tube with a bulb diameter of $1\frac{1}{4}$ inches and a length of 4 inches up to that of the 1,400,000 volt tube of the National Bureau of Standards which is 12 inches wide and 24 feet long. The effective wave length of the radiation generated in such tubes ranges from 0.00025 Angstrom at 100,000,000 volts to 25.0 Angstrom at 1000 volts. (A table showing the relationship of the factors is given.) The efficiency of these tubes increases with the voltage. Whereas at 96,000 volts only 0.2 per cent of the cathode ray energy is transformed into x rays in the target, the measured efficiency reaches 10.4 per cent at 2,350,000 volts. (A table showing the wave lengths and the efficiency relation is given also.) The advantages of Coolidge tubes over others are described.

Further technical developments are as follows:

For roentgenographic tubes

Development of a rapidly cooling tungsten target brazed into a solid or hollow copper block which in turn is cooled by: (1) possessing a large heat capacity; (2) with stagnant or circulating air by means of radiator fins; (3) with water and (4) by a spontaneous or forced circulation of oil passing through the back of the target which in turn is cooled by air or other media.

Development of the line focus: a rectangular focus which by having a slant of 20 per cent (the angle being made by the target surface and the central x ray beam) appears foreshortened in the useful projection, thus equaling a square focus. This line focus is able to withstand the 3 fold load of an ordinary focus of the same projected size. (Values for other angles and curves for load limits are given.)

Development of target sizes varying from 1 to 9 mm. in diameter for different purposes. The allowable loading varies from about 50 to 600 watts per square millimeter.

Development of double focus tubes. Tubes having two foci of different size allow rapid changeover from fluoroscopy to roentgenography which is necessary for the so-called spot film medical roentgenography and other two purpose raying.

Development of a rotating target which allows the constant advance of relatively cold metal to the electron bombardment during a given exposure. In modern rotating target tubes the anode disc rotates with from 3000 to 3500 revolutions per minute. The gain in loading over the stationary target, is then about 10 fold and is generally proportional to the target speed. (A table for the various speeds and exposure times is given.) The line focus principle is maintained in these tubes. Technical difficulties with the target bearings still exist but have been overcome in part by coating the bearing balls with silver or barium.

For therapy tubes

Development of improved cooling of a solid tungsten target which is allowed to heat up to high temperatures. Since an x ray treatment may last for up to an hour the tubes have to be designed for continuous operation. (The focal spot is allowed to be larger than for diagnostic tubes.)

Insertion of a beryllium metal window into the glass wall of the x-ray tube for superficial therapy to allow the passage of very soft x rays from 5 to 10,000 volts for superficial therapy.

The use of thick walled pyrex glass for from 200 to 400 kv deep therapy tubes to prevent the occurrence of punctures.

The use of a metal hooded target to improve the electric field distribution. This will not allow the secondary electrons emanating from the target to reach the glass wall and thus cause punctures. The metal hood may be made to include a beryllium window.

Use of the x ray beam "transmitted" through the target instead of the conventionally used "reflected" beam. This principle is of value for the operation of contact and body cavity tubes. It is a necessary one in the use of supervoltage machines if the voltage is to exceed several million volts because of the peculiar angular distribution of highly penetrating x rays. (Data for the angular distribution at various voltages are given.)

Development of multisectional tubes for 1,000,000 volt machines which allow a more even distribution of the voltage gradient within these tubes by the use of a number of ring shaped electrodes connected to different intermediate voltages. This principle is of special value in the 1,000,000 volt mobile resonance transformer unit in which the tube is surrounded by the transformer coils and the electrodes connected to a number of coil taps.

For diffraction tubes

Use of several windows permitting the simultaneous diffraction or spectrographic study of several specimens. Diffraction tubes operate usually on between 30 and 45 kv and utilize the characteristic radiation of various target metals, e.g. copper and molybdenum.

For all types of tubes:

Development of x ray proof and shock proof tube housings. This more than anything else enables us to enjoy the use of flexible comparatively safe x-ray equipment without which modern radiology is unthinkable.

For all types of tubes:

Development of x ray proof and shock proof tube housings. This more than anything else enables us to enjoy the use of flexible comparatively safe x-ray equipment without which modern radiology is unthinkable.

Most of the described technical advances were made possible only by the Coolidge tube principle.

GERHART S. SCHWARTZ, M.D.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Loutit, J. F., and Mannsall K. The Prevention of Homologous Serum Jaundice *Brit M J* 1945 2:759

Homologous serum jaundice occurs from 40 to 160 days after the introduction of a foreign homologous serum into a recipient. Its occurrence may be accidental, as in so-called syringe jaundice which is believed to result from the injection of traces of foreign blood left in an inadequately cleaned syringe; it may occur following the deliberate injection of serum or plasma as a transfusion or of convalescent serum given as a prophylactic in measles and mumps or following yellow fever vaccination in which human serum is the suspension medium for the killed virus. As to the accidental variety adequate cleaning and sterilization of syringes and needles has been shown to reduce the incidence of jaundice practically to zero. When the introduction of serum is deliberate the prevention of homologous serum jaundice is much more difficult. The yellow fever vaccine problem was solved only by giving up the use of serum as a suspension medium.

This report deals with the results of the introduction of single sera into a number of recipients and a comparison of the incidence of jaundice in these cases with that in a series of cases subjected only to blood transfusions. Blood was drawn from 99 separate donors under sterile conditions, of these 76 had had no previous known attacks of jaundice, 15 had had jaundice apparently from infective hepatitis, for some months to many years previously, 4 had had homologous serum jaundice some months previously, and 4 were donors who had contributed the only blood which had been used for transfusion to a man with hematemeis who 6 weeks later developed jaundice. Of 98 donors followed up for 4 months 94 had no complaints, 3 had bilious attacks, 1 donor had a skin rash, and none had jaundice. Of 602 recipients of sera from the 99 donors 573 could be followed, none of them reported jaundice, but 11 reported bilious attacks and 3 reported skin rashes. It is probable that the bilious attacks and skin rashes were nonspecific in both series.

For comparison 213 patients who had received whole blood or concentrated red cell suspension were studied over a period of 2 months or more. No case of frank homologous serum jaundice occurred in this series although there was 1 case of jaundice diagnosed as infective hepatitis and 1 case diagnosed as hepatitis without jaundice. The findings confirm the impression that homologous serum jaundice occurs only rarely after transfusion with whole blood. This is probably due to the fact that patients receiving transfusions of whole blood alone get homologous material from a few donors only.

In addition to this follow-up only 2 cases suggesting a relationship between whole blood transfusion and subsequent hepatitis have been found. In these cases blood was received from more than 1 donor (4 and 52 donors respectively). It is recommended that for therapeutic and prophylactic purposes the serum used should be from a single individual, or from a few persons only.

JOHN L. LINDQUIST, M.D.

Harrison F. F., and Miller J. K.: The Problem of Hemolytic Streptococcus Carriers in Hospital Personnel. *War Med Chic.*, 1945 8:333

A situation is described in which the occurrence of 2 postoperative infections in aseptic cases seemed to be related to a high hemolytic streptococcus carrier rate among the surgical personnel. The carrier rate was not effectually reduced by chemotherapy. A comparison was made of the incidence of streptococci in the throats of the surgical personnel and of the patients and in the wounds of patients during the winter months of 1944 and 1945.

The authors suggest that as a precautionary measure periodic surveys of the flora of the throats of surgical personnel be made.

WALTER H. NADLER, M.D.

Snell A. M., Wood D. A., and Meisberg, L. J.: Infectious Hepatitis, with Especial Reference to Its Occurrence in Wounded Men. *Gastroenterology* 1945 5:247

Infectious hepatitis has currently manifested itself as three more or less distinct clinical entities: the common epidemic jaundice, postvaccinal (yellow fever) hepatitis and homologous serum jaundice. There is no reason to presuppose any fundamental difference in these conditions, the clinical variations probably being due to the route of inoculation and to the general condition of the affected individual. While the supposed relation of the three syndromes is not proved it is generally agreed that all fatal cases of any of the three types have shown a common picture at autopsy namely that of acute or sub-acute (yellow) atrophy of the liver.

This report deals with the cases of 32 patients who developed jaundice on an average of 84 days following a wound. All of the patients had received blood and plasma at the time of injury and it is believed that the ensuing hepatitis may have resulted from an iatrogenic agent contained therein. Twenty six of the patients recovered, the remaining 6 expiring on an average of 1 week after the jaundice was first noted. The initial symptoms at the time of the appearance of hepatitis were almost identical with those described in ordinary epidemic or catarrhal jaundice. Anorexia, nausea, vomiting, general malaise, and fever were first noted and after an interval of from 1 to 16 days jaundice appeared. Eight

patients, including the 6 who died, developed marked symptoms and signs of involvement of the central nervous system. Surprisingly, the liver and spleen were rarely palpably enlarged in the early stages of the disease. Cephalin-cholesterol flocculation tests were positive in all of the patients at some time during their illness. Although the studies of the hepatic function were limited to those required by medical necessity all of the studies revealed less deviation from the normal than might have been expected. Essential pathological findings in the liver in the 6 fatal cases consisted of an acute autolytic process which was diffuse and most marked in the central and midzonal areas of the liver lobule. Little evidence of regeneration or repair was observed in these cases presumably because of their brief and violent course.

There was no evidence that the disease had been transmitted by droplet infection to other patients in the ward. A laboratory worker who inadvertently drew up a mouthful of serum from a fatal case developed a mild form of the disease 19 days later. There is ample evidence that the preicteric phase of hepatitis may be detected clinically in these cases, as in the experimentally produced variety of the disease. In 1 case it was predicted that jaundice would develop on the basis of two positive cephalin-cholesterol flocculation tests on 2 different days. From this and similar observations it is believed that the cephalin-cholesterol flocculation test becomes positive long before clinical symptoms develop and is probably the earliest evidence of an impending acute hepatitis to be obtained in wounded men.

The authors could not be certain that these cases of severe hepatitis were due to what has been called homologous serum or transfusion jaundice. The incubation period corresponded closely to that seen in hepatitis following yellow fever vaccination and in experimentally produced serum jaundice. The average course prior to the development of serious symptoms in post vaccinal hepatitis is about 36 days as contrasted to 3 or 4 days in this series. Two possibilities suggest themselves as in why the disease should follow so serious a course in the wounded men in this series: (1) that the amount of heterogenic material was very much larger than that transmitted in vaccinal hepatitis or in experimental serum jaundice and (2) that the general nutritional depletion of the wounded men makes them especially vulnerable. The latter view seems the more reasonable.

The essential requirement for the prevention of serum jaundice in wounded men is elimination of the use of blood or plasma containing the heterogenic agent. The practical difficulties of doing this are great. The prevention of fatalities from serum jaundice occurring in wounded men must begin with the maintenance of the general nutrition of the patients and the correction of protein and vitamin deficiencies if such exist. Early detection of the preicteric phase is also a matter of considerable im-

portance as specific treatment may save lives and shorten convalescence. JOHN L. LINCOLN, M.D.

Dorjello, J. R., and Tully, P. W.: The Relationship of Boeck's Sarcoid and Tuberculosis: Report of a Case in Which Tuberculosis of the Lymph Nodes was Associated with Features Highly Suggestive of Sarcoid. *Arch. Path. Chlc.*, 1945 40 300.

Tuberculosis of a cervical lymph node was found in a patient exhibiting no cutaneous reaction to tuberculin. Portions of the lesion presented caseation with acid-fast bacilli in other areas, however the histological picture was indistinguishable from that of Boeck's sarcoid. It is believed that this case lends additional weight to the argument that sarcoidosis, in some instances at least, is an atypical reaction to tubercle bacilli or their products.

That this relationship may occur even though bacilli usually are not demonstrable in the lesions of sarcoidosis is substantiated by the occurrence of the organism free "id" reactions of leprosy and mycotic infections and the generally conceded relationship of streptococci to rheumatic fever and glomerulonephritis. SAMUEL KAHN, M.D.

Kilns, B. E., Miller, J. A., Roach, H. P., and Baumann, G. A.: Certain Effects of Dietary Fat on the Production of Liver Tumors in Rats Fed p-Dimethylaminobenzene. *Cancer Res.* 1946, 6 5

Six groups of 15 rats each were fed 0.06 per cent of p-dimethylaminobenzene for 4 months in synthetic diets containing: (1) no fat, (2) 5 per cent of corn oil, (3) 5 per cent of olive oil, (4) 30 per cent of corn oil, (5) 30 per cent of Crisco, and (6) 30 per cent of lard. Then a dye free diet was given for 3 months. A final incidence of liver tumors of 33 per cent was produced by the low fat diet, as compared with 94 and 33 per cent, respectively when the diet contained 5 per cent of corn oil or olive oil. When 30 per cent of corn oil was fed to the rats, large tumors were present before 4 months and the incidence of tumors at this time was 100 per cent. When 30 per cent of Crisco or lard was given, the incidence of tumors at 6 months was 87 per cent.

These data demonstrate the fact that, in general, p-dimethylaminobenzene is more carcinogenic when the diet contains fat. They show further that the incidence of hepatomas is higher in rats given a diet containing 30 per cent corn oil than in those receiving a diet with 5 per cent corn oil. It is, therefore, apparent, that the level of the fat in the diet, as well as the type of fat, is important for the formation of hepatic tumors by p-dimethylaminobenzene. SAMUEL KAHN, M.D.

Khannolkar V. R., and Suryabai, B.: Cancer in Relation to Usages of New Types in India. *Arch. Path. Chlc.*, 1945 40 351

Three new types of cancer are found in different regions of India namely Bombay, Nagapatam,

patients, including the 6 who died developed marked symptoms and signs of involvement of the central nervous system. Surprisingly, the liver and spleen were rarely palpably enlarged in the early stages of the disease. Cephalin-cholesterol flocculation tests were positive in all of the patients at some time during their illness. Although the studies of the hepatic function were limited to those required by medical necessity all of the studies revealed less deviation from the normal than might have been expected. Essential pathological findings in the liver in the 6 fatal cases consisted of an acute autolytic process which was diffuse and most marked in the central and midzonal areas of the liver lobule. Little evidence of regeneration or repair was observed in these cases, presumably because of their brief and violent course.

There was no evidence that the disease had been transmitted by droplet infection to other patients in the ward. A laboratory worker who inadvertently drew up a mouthful of serum from a fatal case developed a mild form of the disease 10 days later. There is ample evidence that the preicteric phase of hepatitis may be detected clinically in these cases, as in the experimentally produced variety of the disease. In 1 case it was predicted that jaundice would develop on the basis of two positive cephalin-cholesterol flocculation tests on 2 different days. From this and similar observations it is believed that the cephalin-cholesterol flocculation test becomes positive long before clinical symptoms develop and is probably the earliest evidence of an impending acute hepatitis to be obtained in wounded men.

The authors could not be certain that these cases of severe hepatitis were due to what has been called homologous serum or transfusion jaundice. The incubation period corresponded closely to that seen in hepatitis following yellow fever vaccination and in experimentally produced serum jaundice. The average course prior to the development of serious symptoms in post vaccinal hepatitis is about 26 days, as contrasted to 3 or 4 days in this series. Two possibilities suggest themselves as to why the disease should follow so serious a course in the wounded men in this series: (1) that the amount of ieterogenic material was very much larger than that transmitted in vaccinal hepatitis or in experimental serum jaundice and (2) that the general nutritional depletion of the wounded men makes them especially vulnerable. The latter view seems the more reasonable.

The essential requirement for the prevention of serum jaundice in wounded men is elimination of the use of blood or plasma containing the ieterogenic agent. The practical difficulties of doing this are great. The prevention of fatalities from serum jaundice occurring in wounded men must begin with the maintenance of the general nutrition of the patients and the correction of protein and vitamin deficiencies if such exist. Early detection of the pre-icteric phase is also a matter of considerable im-

portance as specific treatment may save lives and shorten convalescence. JOHN L. LUNDQUIST M.D.

Dorogoch, J. R., and Tully, P. W.: The Relationship of Boeck's Sarcoid and Tuberculosis: Report of a Case in Which Tuberculosis of the Lymph Nodes was Associated with Features Highly Suggestive of Sarcoid. *Arch. Path., Chic.*, 1945 40:309.

Tuberculosis of a cervical lymph node was found in a patient exhibiting no cutaneous reaction to tuberculin. Portions of the lesion presented casesation with acid-fast bacilli. In other areas, however, the histological picture was indistinguishable from that of Boeck's sarcoid. It is believed that this case lends additional weight to the argument that sarcoidosis in some instances at least, is an atypical reaction to tubercle bacilli or their products.

That this relationship may occur even though bacilli usually are not demonstrable in the lesions of sarcoidosis, is substantiated by the occurrence of the organism free "id" reactions of leprosy and mycotic infections, and the generally conceded relationship of streptococci to rheumatic fever and glomerulonephritis. SAMUEL KAHN M.D.

Kilne, D. E., Miller, J. A., Rusch, H. P., and Baumann, C. A.: Certain Effects of Dietary Fats on the Production of Liver Tumors in Rats Fed p-Dimethylaminoozobenzene. *Cancer Res.* 1946, 6:5

Six groups of 15 rats each were fed 0.06 per cent of p-dimethylaminoozobenzene for 4 months in synthetic diets containing: (1) no fat, (2) 5 per cent of corn oil, (3) 5 per cent of olive oil, (4) 50 per cent of corn oil, (5) 50 per cent of Crisco, and (6) 50 per cent of lard. Then a dye free diet was given for 5 months. A final incidence of liver tumors of 23 per cent was produced by the low fat diet, as compared with 94 and 53 per cent, respectively when the diet contained 5 per cent of corn oil or olive oil. When 50 per cent of corn oil was fed to the rats, large tumors were present before 4 months, and the incidence of tumors at this time was 100 per cent. When 50 per cent of Crisco or lard was given, the incidence of tumors at 6 months was 87 per cent.

These data demonstrate the fact that in general, p-dimethylaminoozobenzene is more carcinogenic when the diet contains fat. They show further that the incidence of hepatomas is higher in rats given a diet containing 50 per cent corn oil than in those receiving a diet with 5 per cent corn oil. It is, therefore, apparent, that the level of the fat in the diet, as well as the type of fat, is important for the formation of hepatic tumors by p-dimethylaminoozobenzene. SAMUEL KAHN M.D.

Khanolkar V. R. and Suryabai, B.: Cancer in Relation to Usages: 3 New Types in India. *Arch. Path., Chic.* 1945 40:351

Three new types of cancer are found in different regions of India, namely Bombay Visceroplasm

MISCELLANEOUS

441

and Patna. They may be called the dhoti chutta, and khaini cancers. They are associated with the wearing of a light garment (the dhoti) the smoking of a cigar (the chutta) with the lighting end in the mouth, and the depositing of tobacco and lime (khaini) behind the lower lip of the mouth. A histological study of the lesions which precede the development of two of these cancers reveals the similarity of appearance between them and the precancerous stages in mice which have been painted experimentally with carcinogenic substances.

The observations reported and a review of the available experimental literature on the subject of changes in the skin as a result of exposure to mechanical and thermal irritants lead to the conclusion that in the induction of the tumors described the part played by the reaction of the tissues which are the seat of the cancer is equal in importance to that played by the carcinogenic substances themselves.

Saphir, O., Appel, M., and Levinthal, D. H.: At-
tempts to Localize Tumor Metastases in the
Long Bones by Mechanical Trauma. *Cancer*
Res., 1945, 5, 771.

This experimental study was undertaken in order to ascertain whether or not trauma applied to the long bones might be influential in the localization of metastases from a transplanted malignant tumor. The Brown Pearce rabbit tumor, which is highly malignant and readily transplantable into the testes, was used throughout the study. Attempts were made to localize metastases in the long bones by a single mechanical trauma and by chronic irritation. Bone metastases have not been observed in the stock rabbits except in the spinal column, and then but rarely. In order to determine whether or not the Brown Pearce carcinoma grows in long bones transplants were made directly into the femur in 6 normal male rabbits. The tumor grew well within the marrow spaces in all, soon invaded the periosteum and adjacent muscles and metastasized extensively.

Trauma to the bones was produced by simple fracture of the humerus. In a series of 21 rabbits after an intravenous injection of a suspension of tumor cells was made into the ear vein. In a second series of 13 rabbits the humerus was fractured and 24 days later a similar injection was made. In a third series of 12 animals, the tumor was fractured and planted into the testes. Two weeks later after the testicular tumor was easily palpable, the humerus was fractured. In 2 other series chronic mechanical irritation was produced by implanting a small, rough piece of vitallium immediately beneath the tendon of the femur beneath the quadriceps tendon so that with each movement of the leg the metal rubbed against the bone. Six weeks later the intravenous or intratesticular transplantation of tumor was done. Only those animals that died of extensive tumor metastases were considered. Roentgenograms and autopsy studies of the material showed no evidence of tumor cells.

fracture sites or sites of mechanical irritation in any of the animals. It is concluded that mechanical trauma or chronic irritation of the bones played no role in the localization of metastases from transplanted Brown-Pearce carcinoma in rabbits.

DUCTLESS GLANDS

Keller, A. D., Lawrence, W. E., and Blair, C. B.: Effects of Varying Degrees of Hypophysectomy on the Dog. *Arch. Path.*, Chic., 1945, 40, 589.

Varying degrees of hypophysectomy were undertaken in dogs, and the animals were maintained for several months after the operation. During the latter stages of their survival, the status of their carbohydrate metabolism was assayed on a quantitative basis.

Sexual regression, cessation of growth and a marked change in coat were the only effects that could be reliably associated with the removal of the pars anterior per se. The lowering of the carbohydrate reserves, the occurrence and magnitude of the Housay effect and a decrease in adrenal function and size were associated with the progressive encroachment on the hypophyseal stalk, i.e., subsequent to total removal of the pars anterior and the posterior lobe. The greater the encroachment on the stalk, the greater were these deficits. These facts seem to indicate that the pars tuberalis normally elaborates (presumably in common with the pars anterior) the autacoids which are essential for the maintenance of these functions.

There was essentially no accumulation of fat in the livers of animals showing a nearly maximal Housay phenomenon. Obesity occurred following (1) hypophysectomy per se (2) lesions restricted to the hypothalamus (3) hypophysectomy plus encroachment on the hypothalamus and (4) section of the stalk plus encroachment on the hypothalamus. The obesity which followed hypothalamic involvement was definitely pathological, and that following hypophysectomy per se was also believed to have a pathological component. Obesity was not encountered when the surgical procedure was limited to section of the hypophysis or selective removal of the hypophyseal stalk.

In certain instances, in which there was gross infringement on the hypothalamus in addition to total removal of the hypophysis, the deficits in carbohydrate metabolism and adrenal function were submaximal or did not deviate materially from the normal. This suggests the possibility that endocrine principles are elaborated in the immediate environs of the hypothalamus, and that these principles have actions contrary to the actions of the known hypophyseal principles.

The term "hypophysectomy" therefore should not be used indiscriminately. In carrying out work to describe the type of hypophysectomy not only anatomically but

EXPERIMENTAL SURGERY

Kinney, T. D., Haynes, F. W. and Dexter, L.: Experimental Production of Pulmonary Embolism by the Use of a Venous Catheter. *J. Lab. Clin. M.* 1945 3

To evaluate various methods of therapy for severe thermal burns in rats, the authors have devised a standard burn procedure. This has made it possible (1) to obtain reproducible survival rates (2) to preserve uninjured extremities (3) to eliminate the complication of trauma and hemorrhage from autoincision and (4) to preserve uninjured body orifices and permit the voiding of urine and defecation.

The success of the method is dependent on the standardization of all possible conditions. The Wistar rat was used as the test animal and kept under conditions of controlled temperature humidity and diet. The food and water intake after the burn had been given was also controlled.

A scald burn of the back was produced on anesthetized rats by immersion for 15 seconds at $90 \pm 0.25^\circ\text{C}$. A series of burns was produced from the base of the skull to the base of the tail, with the lateral and ventral burned area sharply demarcated and removed in order to calculate the percentage of total body surface burned. By varying the curvature of the back on immersion the burned

area can be varied from 45 to 10 per cent. In practice it was found that within this range 75 per cent of the surface burn could be reproduced within ± 2 per cent.

In order to obtain reproducible survival percentages for any given percentage of burn area, the initial weights of the burned rats were within a closely selected weight band. Two weight bands have been studied extensively: (1) from 200 gm. and (2) from 200 to 210 gm., and in these two groups all rats receiving burns of 50 per cent or more of the total body surface have survived within 48 hours while all rats receiving burns of 40 per cent or less of the total body surface have survived. The group receiving a burn between 40 and 50 per cent of their total body surface have a 34 per cent survival percentage for the entire weight groups of 54 per cent.

No significant difference was found in the relationship of the sex to survival.

Manipulation such as handling of the burned rat to obtain blood samples, markedly influenced survival. The 50 unhandled rats showed a 44 per cent survival while 50 which were subjected to intracutaneous samplings (7 per animal) showed a 34 per cent survival.

Reproducible survival rates depend on the control of all possible factors, such as the temperature of the bath, time in the bath, weights of the animals, finally seasonal variations for unburned controls. They cause a statistically significant difference in the cause of the sensitivity of the method to changes in any one of several variable factors. It is recommended that simultaneous controls always accompany the experimental groups.

OBSERVATIONS ON RADICAL SURGERY FOR LESIONS OF THE PANCREAS

ALLEN O. WHIPPLE, M.D., F.A.C.S., New York, New York

IT is now ten years since an effort (28) was begun to revive previous sporadic attempts at operating on malignant tumors involving the ampullar area and the pancreas. Since then considerable progress has been made in the evolution of the surgery of this region and organ. It is the purpose of this paper to discuss the factors that have made possible this progress and to call attention to mistakes to be avoided and to certain safety factors that have been found to insure a satisfactory result in the several procedures that can be used as indicated by the present pathology. The diagnosis of these lesions is not discussed in this paper.

The phase of surgery of the pancreas dealing with the removal of islet cell tumors for hyperinsulinism—a most interesting chapter in itself—had a determining influence in developing the radical surgery for malignant tumors. For it was demonstrated that with the use of silk for ligature and suture material with the delicate handling of tissue that such technique requires it was possible to carry out safely and with little reaction limited or extensive excision of pancreatic tissue. Thus the pre-existing dread of the pancreas as a source of surgeons was removed and the confidence of surgeons was increased in attacking the malignant lesions *en bloc*.

From the Department of Surgery, Columbia University, New York.

The history of previous efforts to deal radically with the tumors involving the duodenum, the common duct and the pancreas is worth reviewing because it emphasizes the grave dangers and the serious complications which deterred surgeons in the past from continuing attempts to deal with these lesions. It must be remembered that these surgeons did not know of the advantages of vitamin K blood transfusion and other shock prevention therapy and did not appreciate the significance of the principles of silk technique.

HISTORICAL REVIEW

The first successful attempt to remove an ampullar growth with excision of a segment of duodenum and a portion of the pancreas around the ampulla with implantation of the pancreatic and common duct in the line of suture of the repair of the duodenal defect was accomplished by William S. Halsted in 1899. His patient developed a stenosis of the common duct after 3 months was reoperated upon a choledochostomy being performed but died 6 months later. Autopsy revealed recurrent carcinoma in the head of the pancreas and duodenum.

Mayo-Robson in 1900 and Koerte in 1904 removed cylindrical segments of the duodenum including an ampullar carcinoma but the patients did not survive the procedure. In 1907 Desjardins described an operation for

WHIPPLE RADICAL SURGERY FOR LESIONS OF PANCREAS

Fig. 1. Variations in extent of the uncinate process in relation to superior mesenteric vessels.

head which is described in the anatomy of the pancreas. This may be absent or be so developed as to encircle completely the superior mesenteric vessels and the portal vein (Fig. 1). Furthermore, its relation to those vessels, even as the duodenum with the head of the pancreas has been mobilized, is the superior mesenteric vessels as they pass over the terminal portion of the head of the pancreas to pass behind or surrounding them, done from the neck of the pancreas void injury to the superior mesenteric, and the terminal splenic vessels, each will make it possible to separate safely. This approach also facilitates identification of the pancreaticoduodenal and tributaries from the pancreatic bed.

Regarding the resections of the pancreas and chronic inflammation, uncontrollable pain the decision as to of the organ is to be removed is by the pathology as shown by films for calcification, and by the and induration are limited to tail the head of the organ with the duodenum be left intact. If the pathology is indicated with the same one stage as described for an ampullar neoplasia the pathology involves all parts of and duodenectomy is the operation will result in a diabetes of smaller doses of insulin of diabetes mellitus. A total pancreatectomy is indicated by several surgeons of months to warrant indications of leakage, during these radical pro-

cedures from the common duct and pancreatic duct, it is essential to establish adequate drainage of the denuded retroduodenal area. This is best accomplished by a good sized soft rubber tube with wide openings containing a smaller rubber tube to which continuous suction can be applied. The outer tube with several lateral openings prevents the suction tube from attaching itself to adjacent tissues and insures prompt and constant emptying of any exudate or secretions that otherwise would collect in the subhepatic space or Morrison's pouch. This has two other advantages: it prevents the soaking of the dressings with fluid that may have irritating and digestive action on the patient's skin; it makes it possible to measure the loss of fluid and electrolyte which in some cases may be 1 or 2 liters daily in the first week of the postoperative period.

PREOPERATIVE CARE

Measures to determine and to treat the cardiovascular, renal, and hepatic dysfunction are essential in all radical pancreatic surgery. The jaundice in many of these patients, if of several weeks' duration, may accompany renal and hepatic damage and in the older patients myocardial impairment is frequently present. Electrocardiographic studies are frequently indicated. Digitalis therapy. Nitrogen and dye retention as well as bladder retention due to prostatic hypertrophy require preoperative treatment. Prolonged prothrombin and clot

Fig. 2. Antecolic anastomoses with loop of jejunum.

ting time demand intensive vitamin K medication preferably by dysis. Failure of the prothrombin time to return to normal is an indication of severe liver damage and adds materially to the danger of the immediate postoperative period. It is advisable to give 25 000 units of penicillin every 4 hours for 24 to 36 hours before operation to combat gram positive bacterial infection in the operative field. Preoperative transfusion of blood is usually indicated. A Levin or Wangenstein tube should be placed in the stomach before operation to be used for suction after the operation.

ANESTHESIA

The choice of anesthesia is largely determined by the preoperative study. An experienced and skillful anesthetist is essential and he should be consulted as to the choice of anesthetic in the individual case. In our experience gas oxygen ether general or continuous spinal has given the most satisfactory and safe anesthesia. The radical operations are 4 hour procedures and require administration of anesthesia by skilled technicians as well as administration of supportive form of continuous infusion of saline infusions of 1500 cubic centimeters of the latter.

Fig. 3. Antecolic or postcolic anastomoses with loop of resected jejunum.

dicating the steps and stages of the operation. Certain points in the anatomy and technique will be discussed in more detail.

Incisions. The incision (Fig. 5) upon the procedure indicated. For the incision of the duodenum and head of the pancreas a right rectus incision from costal margin to the umbilicus gives adequate exposure and avoids the contamination of a long transverse incision. For resections of the entire jejunum or body and tail, or for exploring the jejunum for islet cell tumors the curved transverse incision above the umbilicus through the rectus abdominis and into the oblique muscles is essential. A left rectus incision is mentioned only as inadequate and handicapping.

QUESTIONS

2, 3, 4) showing surgical procedure.

The illustration shows three types

WHIPPLE RADICAL SURGERY FOR LESIONS OF PANCREAS

629

Fig. 5. Incisions used in radical resections of the pancreas.

anastomoses with vertical limb of resected jejunum following total pancreatectomy duodenojejunostomy

the duodenum to midline to determine the site of the head of the pancreas. A study of the emergence of the pancreatic vessels from behind the superior mesenteric vessels from behind the head of the pancreas is carried out to determine the site of the uncinate process and the degree of encirclement of the superior mesenteric vessels.

The common duct is separated from the portal vein in the gastrohepatic or hepatoduodenal ligament well behind the pancreatic duct and behind the duodenum where it is to be divided between the stomach and the duodenum.

The stomach is divided between the pylorus and the duodenum by Payr clamps.

The gastroduodenal artery is identified and the hepatic artery is identified which it arises from.

Depending upon the location and extent of the tumor and the presence or absence of the uncinate process the duodenum is divided proximal or distal to the duodenojejunostomy. If a carcinoma of the pancreas is present or if the tumor passes behind the superior mesenteric vessels great care must be used in dividing the duodenojejunostomy junction to the mesenteric root vessels.

In this exposure the inferior pancreaticoduodenal artery can be identified and ligated. The pancreas is now divided anteriorly at the junction of head and body and the splenic vessels and portal vein identified and the portal vein and superior mesenteric vessels carefully dissected away from the head of the pancreas. This is especially important if the uncinate process encircles the superior mesenteric vessels. The head of the pancreas is removed *en masse*. If the duodenum is divided proximal to the duodenojejunostomy an over and over suture and this closure buried with interrupted mattress or fine chromic continuous suture and this closure buried with interrupted mattress or fine chromic continuous suture and this closure buried with interrupted mattress or fine chromic continuous suture.

The distal cut end should be closed with interrupted silk. If the jejunum is divided distal to the duodenojejunostomy the jejunum is divided distal to the duodenojejunostomy and is brought up through the rent in the mesocolon to be used for the necessary anastomosis. If the duodenum has been closed either a loop of jejunum can be used anteriorly for the anastomosis or a vertical limb of the jejunum divided below the mesocolon can be brought up behind or in front of the mesocolon for the anastomosis to be followed by an end-to-side Roux-Y jejunostomy. The

ling time demand intensive vitamin K medication preferably by clysis. Failure of the prothrombin time to return to normal is an indication of severe liver damage and is an materially to the danger of the immediate postoperative period. It is advisable to give 25 000 units of penicillin every 4 hours for 24 to 36 hours before operation to combat gram positive bacterial infection in the operative field. Preoperative transfusion of blood is usually indicated. A Levin or Wangenstein tube should be placed in the stomach before operation to be used for suction after the operation.

ANESTHESIA

The choice of anesthesia is largely determined by the preoperative study. An experienced and skillful anesthetist is essential and he should be consulted as to the choice of anesthetic in the individual case. In our experience gas oxygen ether general or continuous spinal has given the most satisfactory results. The radical operations and safe anesthesia. The radical operations are 4 hour procedures and require administration of anesthesia by skilled technicians as well as administration of supportive intravenous fluids in the form of continuous drip saline infusion and 500 to 1500 cubic centimeters of matched blood transfusion during the latter part of the operation.

OPERATIVE TECHNIQUES

The illustrations (Figs. 2, 3, 4) showing the three types of one stage radical procedures in

Fig. 3. Antecolic or postcolic anastomoses with vertical limb of resected jejunum.

dedicate the steps and stages of the operations. Certain points in the anatomy and techniques will be discussed in more detail.

Incisions. The incisions (Fig. 5) depend upon the procedure indicated. For the resection of the duodenum and head of the pancreas a right rectus incision from costal margin to the umbilicus gives adequate exposure and avoids the contamination of a long transverse incision. For resections of the entire pancreas or body and tail or for exploring the pancreas for islet cell tumors the curved transverse incision above the umbilicus through both recti and into the oblique muscles is essential. The left rectus incision is mentioned only to condemn it as inadequate and handicapping.

TECHNIQUE OF THE ONE STAGE PROCEDURE FOR CARCINOMA OF THE AMPULLAR REGION

Incision. Right rectus incision is made from near ensiform to below umbilicus.
1st step. Careful review of the head of the pancreas, duodenum gastrophatic omentum and liver is carried out to determine presence of metastases.
2nd step. Incision of the peritoneum is made to the right of the duodenum with ele

Fig. 6. Illustrations of repair of the incision and drainage tube to be used

wings (Figs. 2 and 3) illustrate these modifications.

9th step End-to-side gastrojejunostomy is performed.

10th step The dilated pancreatic duct is approximated into the jejunum above the gastrojejunostomy; a goiter or Carrel rubber tube being used to connect the pancreatic duct with jejunal mucosa through a 5 millimeter opening in the wall of the jejunum. The rest of the stump of the pancreas is to be tacked to the jejunal wall with interrupted silk sutures (Figs. 2 and 3).

11th step End-to-end or end-to-side choledochojejunostomy is performed depending upon the use of a loop or a limb of jejunum. A posterior layer of fine silk is used for seroserosal suture followed by an over-and-over continuous fine chromic suture to unite the mucosae and walls of the duct and jejunum, followed by the anterior seroserosal suture. If there is any tension whatsoever on its anastomosis the gall bladder or the hepaticoduodenal ligament should be tacked with interrupted silk sutures to the jejunal loop or limb to relieve tension. If a limb has been brought up behind the colon the rent in the mesocolon should be tacked to the vertical limb of jejunum to close the opening and prevent herniation. If a loop has been used

for the anastomoses the distal portion should be used for the gastrojejunostomy so as to avoid gastric contents from flowing over the common duct and pancreatic duct anastomoses.

12th step Peritoneal toilet sponge and pad count are made and a careful review of the hemostasis.

13th step The perforated rubber tube with inner suction tube is placed in the subhepatic area away from the anastomoses to collect seepage and leakage of bile etc.

14th step Near and far steel wire sutures through all layers of the abdominal wall with interrupted fine silk mattress sutures for peritoneum and posterior rectus sheath are placed and tied before the steel wire sutures are tied or twisted to approximate the edges of the incision (Fig. 6B). The wire sutures should be left in place for 12 to 14 days. The long segment of each wire suture should be cut at each end near the skin. (Fig. 6D). The next day the twisted wire can be removed easily.

It should be emphasized that a slow transfusion should be started as soon as the patient is found operable and continued during the procedure using if necessary 1000 to 1500 cubic centimeters of blood. It is a long trying operation and depending upon the build of the patient and the presence of fat in the upper

WHIPPLE RADICAL SURGERY FOR LESIONS OF PANCREAS

631

abdomen and mesenteries the time of the procedure will vary from $3\frac{1}{2}$ to 5 hours.

PRIMARY SUTURE OF NERVES

R. B. ZACHARY F.R.C.S. and W. HOLMES, M.A. D.Phil. Oxford, England

THE distinction between a primary and a secondary nerve suture is fairly generally understood, but the precise definition of the terms presents some difficulties. If a time limit is used the criterion for example, suture within 12 or 48 hours, some cases would be wrongly included from the group of primary sutures though the nerve repair were undertaken the time of the first surgical treatment of wound. In peace time this operation is usually done within a few hours but during the wound excision may not be done for 3 or more days when the direct local effects of the trauma are still in evidence and there has been no tissue repair. It is clear the environment of a sutured nerve at this stage is more closely allied to that which prevails in the immediate post-traumatic period than to the conditions obtaining when the wound has healed and a nerve repair performed in such circumstances would still be a primary nerve suture. For the purposes of this paper we define primary suture as the repair of a nerve through original unhealed wound at the time of the operative treatment of the wound itself.

The earliest record of nerve suture is of a repair of the median and ulnar nerves attempted by Baudens in 1836 (Létiot 1873). Contact of the suture material with the nerve was avoided to prevent necrosis and approximation of the nerve ends was accomplished by suturing the adjacent tissues. Unfortunately the patient died 8 days later and the nerve ends were found to have separated.

There is no evidence that the operation was repeated until nearly 30 years later then in 1862 more sutures were reported the first by Nélaton (Houel, 1864) the second by Laugier (1864). Both were primary sutures and in each case it was claimed

that motor and sensory recovery followed within a few days of operation. Howell and Huber (1893) collected records of 84 primary sutures they concluded that after primary suture the prognosis is favorable. Function will probably be restored completely or partially. They also added that after secondary suture the prognosis is good improvement is almost certain and in a large proportion of cases complete success may be expected. In comparing the results of primary and secondary suture they were concerned mainly with the problem of first intention healing of nerves. The view has been remarkably persistent that primary repair of nerves leads to healing by first intention and early clinical recovery at a rate incompatible with degeneration and regeneration of the distal trunk, and as late as 1923 at the International Congress of Surgery in London Henrikson reported such a case. But there is no doubt that in all examples of apparently immediate recovery many of which have come under our observation the sensory 'recovery is due to overlap from adjacent nerves and the motor recovery' to anomalous innervation or trick movements. The hypothesis of first intention healing is now exploded.

Another review of a series of primary sutures was that made by Sherren (1908) who examined 50 cases. Recovery of pain sensibility started between the 5th and 25th week, and touch sensibility between the 19th and 46th week the longer delay was in some cases ascribed to suppuration. He stated that restoration of tactile localization was not as a rule complete until more than 2 years after suture sometimes longer and that all cases uncomplicated by suppuration regained perfect sensibility. He found that motor power returned in about 1 year after suture of the ulnar nerve at the wrist and following suture at the elbow. He specified the quality of the suture material used in reviewing the older cases of

Holmes is Beit Memorial Fellow from the Department of Orthopaedic Surgery (Peripheral Nerve Injury Centre) and the Department of Zoology and Comparative Anatomy University of Oxford.

performed at the London Hospital he found only one in which there had been no recovery—a patient whose wound became infected. Sherren advocated primary suture of divided nerves because the prognosis after secondary suture is more unfavorable.

Platt and Bristow (1923) in reviewing the late results of nerve injuries of the war of 1914-1918 refer to the extreme perfection attained after so called primary sutures and the incomplete type of recovery which is the rule in the majority of secondary sutures. They ascribe the difference to the type of lesion—the nerve was more seriously damaged in gunshot wounds and these all came into the class of secondary sutures.

Gonzalez Aguilar (1928) advocated suture as soon as possible after the myelin remains had been removed from the distal stump at the time when Schwann cells exhibited their maximum activity the optimum time for suture in his opinion is about 30 days after division of the nerve.

Herbig (1937) reported 4 primary nerve sutures; 2 were followed by complete recovery, 1 by improvement and there was 1 failure. In a series of 13 secondary sutures performed 2 to 12 months after injury 5 were cured and 8 improved there were no failures. His conclusion that primary suture gives the best results does not seem reasonable from these figures.

Platt (1937) refers to a series of 12 primary sutures. Although he does not give the results in detail he concludes that in primary sutures performed under ideal conditions complete recovery of motor power and recovery of protopathic sensibility at least is to be expected. In secondary sutures partial or complete motor recovery with imperfect restoration of sensation has been the rule. He advocates primary suture in small relatively clean wounds. In more extensive wounds with widespread bruising and multiple tendon injuries and in wounds in which infection has already secured a hold partial or complete failure after primary suture is almost inevitable.

Many other authors (Pollock and Davis 1933, Galile 1942) hold similar views but Mitchiner (1939) advises primary nerve

suture in gunshot wounds even in the presence of moderate infection.

During the Spanish Civil War Jolly (1942) carried out a number of primary nerve sutures but gave up this practice on the advice of Diaz who had found that the results of secondary nerve suture were better.

From the accounts of these authors it would appear that the chief factor militating against the success of a primary suture is infection and although many would hesitate to undertake primary nerve repair when in statement of Pollock and Davis that if primary nerve suture is performed and the wound remains clean and heals by primary intention we have taken advantage of the best possible conditions under which the end suture may be performed.

The investigation of nerve suture by animal experiments performed under aseptic conditions has shown that an optimal functional result is given by primary suture and that delay in repair progressively prejudices the quality of recovery. However the only primary sutures in man comparable with those carried out experimentally are those performed when a nerve is divided either accidentally or deliberately during the course of an operation. The conditions prevailing when suture is performed immediately after an incised lacerated or gunshot wound are different in many ways from those prevailing in an experimental or accidental operative section and the following analysis of the results of primary repair performed under a variety of conditions has been undertaken with a view to determining the policy to be adopted in the early treatment of divided nerves.

MATERIAL AND METHOD OF INVESTIGATION

Material. In this series are included all the cases of primary nerve suture which have come under observation at the Peripheral Nerve Injury Centre at the Wingfield Morris Hospital Oxford during the years 1940-1944. We have excluded all those in which the surgeon aimed at nothing more than a rough approximation of the stumps at the primary operation. There were 55 primary nerve

SURGERY GYNECOLOGY AND OBSTETRICS

2. The term "Laceration" includes lacerated or incised wounds.

ures in 49 patients. In 3 the nerve was usually divided at operation and immediate suture was undertaken. Fourteen were sutured during the primary treatment of gunsbot wounds and 38 during repair of incised or lacerated wounds. The ults in these cases demand special attention (Table I)

pattern and quality of recovery after suture depend to a certain extent on the involved and for this reason lesions of individual nerves will be considered separately before a final review is attempted. A variable factor that must be allowed in the analysis is the site of the lesion. Recovery after suture of the median or ulnar nerve in the arm is nearly always less satisfactory than after suture in the forearm and the results in these two nerves are therefore considered separately for high and low sutures. In the early days of this work those patients whose nerves had been sutured at the primary operation were not subjected to exploration unless there was some very good reason for doing so such as the absence of any sign of recovery long after it was due. Thus the cases in this group have been under observation for a considerable

time—up to 4 years—ample time for recovery to reach a stage at which it could reasonably be compared with that observed after secondary suture. More recently after it had been found that a number of primary nerve sutures had not been followed by satisfactory recovery the policy was changed and on a number of occasions exploration was undertaken at an early date. In 16 cases resection and resuture were performed. In some of the cases subjected to reoperation sufficient time had elapsed for recovery to be apparent and the quality of such recovery as had occurred will be indicated. To a certain number however exploration and resuture were undertaken before any clinical signs of regeneration could be expected and in these the data on which the assessments of the success, or otherwise, of the primary suture are based are histological—not clinical.

Clinical grading of recovery. In 1942 the Medical Research Council adopted a scheme for the assessment of recovery in peripheral nerve injuries suggested by Highet (Highet and Holmes, 1943). This system has a neurological basis, and motor and sensory recovery are considered separately. Although the scheme provides a valuable foundation it has been found necessary for our purposes to introduce certain intermediate grades in the assessment of ulnar, median and radial palsies. For example after a high lesion of the median nerve the recovery of slight power in the long flexor muscles is described as grade 1½ yet another patient who shows considerable strength in the long flexors but has not yet regained voluntary power is the not yet regained voluntary power is the thenar muscles comes into the same low category. Similarly with the ulnar nerve a patient who has recovered only slight voluntary power in the hypothenar muscles is classified as grade 2 which is the grading for another patient who has regained voluntary power in all the intrinsic muscles though not sufficient to act against resistance. It is necessary to introduce intermediate grades for each nerve and the following system has been adopted in this paper. It is presented at length herein since others may find the classification of use in the accurate assessment of recovery.

ULNAR NERVE

Motor Recovery

- M 0 No contraction in any muscles
 M 1 Return of voluntary power in the proximal (long flexor) muscles although they are not able to act against gravity
 M 1+ The proximal muscles act against gravity
 M 2 The proximal muscles are acting and there is a contraction in the hypothenar muscles at least with either no action in the interosseus or not more than a flicker
 M 2+ The proximal muscles and the intrinsic muscles are all acting and the first dorsal interosseus muscle produces a definite movement but does not act against resistance
 M 3 The long flexor muscles the hypothenars and the first dorsal interosseus act against resistance.
 M 4 As in grade 3 but some independent lateral movement of the fingers is possible
 M 4+ Recovery to grade 4 but the independent movement is good although not perfect.
 M 5 Complete recovery

Sensory Recovery

The subdivisions are the same as for the median nerve and will be dealt with under that heading

MEDIAN NERVE

Motor Recovery

- M 0 No contraction in any muscles
 M 1 A definite contraction in the proximal (long flexor) muscles but they do not act against gravity
 M 1+ The proximal muscles act against gravity but there is no return of power in the thenar muscles
 M 2 The proximal muscles act against gravity and there is a flicker in the thenar muscles
 M 3 The thenar muscles act against resistance
 M 4 All muscles act against strong resistance and some independent action is possible.
 M 5 Full recovery in all muscles

Sensory Recovery

- S 0 No recovery of sensibility in the autonomous zone of the median nerve
 S 1 Recovery of sensibility in the autonomous zone of the median nerve
 S 1+ Recovery of deep cutaneous pain sensibility within the autonomous zone of the median nerve
 S 2 Recovery of superficial pain sensibility
 S 2+ Recovery of superficial pain and some touch sensibility throughout the median area but with over response
 S 3 Recovery of pain and touch sensibility with disappearance of over response
 S 3+ Recovery as far as S 3 but localization of the stimulus is good and there is imperfect recovery of two-point discrimination.
 S 4 Complete recovery

RADIAL NERVE

Motor Recovery

- M 0 No recovery

- M 1 Return of voluntary power in the proximal muscles but not sufficient power to act against gravity
 M 1+ Return of power to the proximal muscles sufficient to act against gravity no return in the muscles acting on the thumb
 M 2 Return of voluntary power in the proximal muscles and the muscles acting on the thumb but the latter are not able to act against resistance
 M 3 Recovery to M 2 but abductor pollicis longus and extensor pollicis longus act against resistance.
 M 4 Proximal and distal muscles are acting strongly against resistance and some independent movement of the fingers is possible
 M 4+ Independent movement very good but not perfect.
 M 5 Complete recovery

Sensory Recovery

Intermediate grades as for median nerve may be used.

Although both motor and sensory recovery will be indicated in the tables giving the results of primary suture it is clear that for the ulnar and radial nerves motor recovery is the more important and should be used as the chief criterion for comparison, whereas for the median nerve good sensory recovery is of chief importance

One further point must be made clear before presenting the results. Previous authors have been impressed by the poor quality of recovery after secondary nerve suture as compared with primary which is not surprising if all secondary sutures are taken into account. Such a comparison is not of great value since it would include consideration of many nerve injuries for which primary suture would have been quite impossible for example those in which there was a large gap. It would also include many cases in which there was an unnecessarily long delay for recovery because at the primary operation the nerves were not seen to be divided and also in cases complicated by prolonged sepsis. Such delay leads to profound changes in the nerve, the end-organs and muscles, changes which adversely affect the quality of recovery. A better idea of the value of primary suture is obtained by comparing the quality of recovery with that seen after early secondary repair of lesions in which the gap was not so

4 C 30 30	Gunshot	Muscle damage and median nerve division	A few hours	+	cm. above medial epicondyle	—	None	20	Separation of suture. Re-suture.

Further recovery probable.

large that it would have precluded primary suture. Some arbitrary classification must be made both as regards extent of the gap to be closed and the interval that elapsed before suture. For purposes of comparison we have thought it reasonable to use those secondary sutures performed within 6 months from the date of injury in which the gap was less than 6 centimeters. There must be few wounds in which primary nerve suture is feasible which are not fit for the secondary operation within six months.

RESULTS

Clinical Review

a Clinical review of results of primary nerve suture—High ulnar sutures (Table II) The quality of recovery after primary suture of the ulnar nerve above the elbow was not good but recovery of power in the intrinsic muscles of the hand is usually poor after high lesions, whether suture is performed early or late. In 2 of the 6 cases (1 and 3) the final stage of recovery had been reached—in Case 1 the result was moderate and in Case 3 poor.

Low ulnar nerve sutures (Table III) There were 20 cases in which the ulnar nerve was sutured in the forearm at the primary operation. In Cases 22 to 26 resection and resuture were performed before any appreciable re-

covery could have been expected. In Case 21 suture was of the sensory division only and one patient (Case 20) drowned before there was time for recovery to be well advanced.

The remaining 13 cases had sufficient time to show a considerable degree of recovery. Of these 2 (Cases 7 and 8) reached grade M₄ in which some independent lateral movement of the fingers was possible. One was a boy aged 7 years which is significant since it has become clear from a study of many nerve injuries that the rate of recovery is more rapid and the quality better in children than in adults. Two others reached grade M₃. Three patients recovered to grade M₂. In one of these an anomalous branch was found arising above the lesion and joining the nerve again below the site of division. The sparing of this branch might have enhanced the quality of recovery. In Case 13 the primary suture was performed at the Wingfield Morris Hospital and the lesion was re-explored 19 months later because recovery was not proceeding satisfactorily. There was a large neuroma at the site of suture.

In the remainder the recoveries were poor although in Cases 14, 15 and 16 the assessment must not be regarded as final.

Median nerve sutures (Table IV) There was only one primary suture of the median nerve

above the elbow and there has not yet been time for recovery to be well advanced.

In 17 patients primary suture was performed on the median nerve in the forearm.

In 13 sufficient time had elapsed for substantial recovery to occur. In 3 the grade of recovery was very good with return of touch sensibility throughout the median area of a

*Further improvement probable.

degree sufficient to localize the stimulus and to distinguish the points of a compass less than 1 centimeter apart. One of the patients was a girl aged 5 years. In 3 others two-point discrimination and localization did not return so well but there was no over reaction to pin prick. In Cases 35 and 36 there were moderate sensory recoveries but in the remaining 5 recoveries were poor although further improvement might occur in 2. In 6 patients (including 2 mentioned above) the site of primary suture was explored and secondary suture undertaken. They will be considered later.

Radial nerve sutures (Table V) There were 7 cases of primary suture. In 5 sufficient time had elapsed for some degree of recovery to be apparent in 2 re-exploration and suture were performed at an early date.

Of the 5, 1 showed good recovery, 1 moderate, and 2 fairly poor. The last 2 may improve further since they have been followed for only 15 and 18 months respectively. There was one failure.

Sciatic nerve sutures (Table VI) In 3 patients the posterior tibial nerve was sutured at the primary operation with recovery of touch and pain sensibility but persistence of overreaction to pin prick. There was only 1

patient in whom the main trunk of the sciatic nerve was sutured at the primary operation. The site of suture was explored and resected before recovery could have occurred and this case is considered in the histological section.

There were no primary sutures after wounds involving the lateral popliteal nerve.

Comparison of results of primary and early secondary sutures The results of primary and early secondary sutures of the ulnar nerve above the elbow are shown in Table VII. Most of the gradings are not final but it does not appear likely that the results of the final comparison will be significantly different. In none was there motor recovery to grade M 3.

Low ulnar nerve sutures (Table VIII) have good and poor results in both groups, but it is clear that the general standard of recovery after secondary suture is better than after primary suture. Two out of 13 primary sutures had reached grade M.4 compared with 4 out of 12 secondary sutures. Four primary sutures had reached the stage at which the intrinsic muscles were acting against resistance (M 3) whereas 8 secondary sutures had reached this grade. Although there are 3 primary sutures in which further progress is likely, 4 secondary sutures should improve still further.

TABLE VI.—PRIMARY SUTURES OF SCIATIC NERVE

Case No. File No. Age	Type of wound	Associated lesions	Primary suture suturing Time after injury	Sepsis	Site of suture	Recovery		Secondary operative findings
						Grade	Days after suture	
(a) Males W 7 50	sciotic wound Laceration	Muscle damage	3 hrs.	+	Lower border of gluteus maximus	None	190	Separation, re- suture
(b) Females G 15 30	labial nerve Gunsheut	—	5 min.	—	Below motor branch	S	100	
54 S 4 24	Laceration	—	7 hrs.	—	4 cm. above medial condyle	S	100	
55 L 14 24	Gunsheut	—	7 hrs.	—	Partial division 5 cm. above medial condyle	S.2	1250	

Three of the 9 secondary sutures of the median nerve (Table IX.) reached a high grade of recovery compared with 3 out of 13 primary sutures. Six out of the 9 had reached grade S3 compared with 6 out of 13 primary sutures. The contrast between these two groups is not striking but the balance is in favor of the secondary sutures. Four of the latter have not yet reached their final stage and 3 primary sutures may show some improvement later.

The high quality of recovery after early secondary suture of the radial nerve is at once apparent (Table X.) Six out of 8 secondary sutures reached grade M4 compared with

one out of 5 primary sutures. Further improvement is likely in 2 secondary sutures and also in 2 primary sutures. Allowing for the recovery of these sutures to the next grade, the balance would still be strongly in favor of the early secondary sutures.

Two early secondary sutures of the posterior tibial nerve resulted in recovery of a similar grade to that after primary suture, but the value of comparing recoveries of this nerve is probably not great, on account of the difficulties in grading sensibility on the sole of the foot.

The comparison between recoveries after primary and secondary suture is set out in the histograms (Figs. 1, 2, 3) in which the motor or sensory recovery is plotted along the abscissa and the number of cases is plotted along the ordinate. The method has limitations since the time interval after suture is omitted, but an indication is given of the cases likely to show further recovery i.e. where the assessment was made less than six hundred days after operation.

Now that the data in each group have been presented we can depict the results in the whole clinical series in the form of a single composite histogram. For this purpose we have recorded the motor recovery of the ulnar and radial nerves and the sensory recovery of the median nerve on the same histogram. The result is shown in Figure 4, in which the more uniformly good results after early secondary suture are at once apparent. The number of recoveries to grade M4 or S3 after secondary suture is 16 out of 34 with 7 intermediate re-

coveries of lower quality. In the group of primary sutures 9 out of 39 had reached the same high grade with 9 other recoveries at an intermediate stage. However even in the incomplete recoveries the quality is higher in the early secondary sutures 9 out of 11 intermediate recoveries in the early secondary sutures had reached M 2+ or S 2 whereas none of the corresponding primary sutures had recovered so far.

c Associated factors. Why do these results not bear out the theoretical superiority of primary nerve suture over later repair?

What adverse factors may have impaired or prevented recovery?

Age. Two primary sutures were performed on children aged 7 and 5 years respectively (B.40 and O.10) and both resulted in a high grade of recovery. The influence of youth on the quality of recovery is shown by another case not in this series. A girl aged 9 years sustained a division of the median nerve which was repaired 3 years later. Eighteen months after operation there was recovery to M.4 S.3+ equal to that of the best primary suture. There were no children in the group of early

Fig. 1. Histogram showing recovery after primary and early secondary sutures of the ulnar nerve. In all histograms cross hatched area indicates intermediate grade of recovery; black area, final grade of recovery.

secondary sutures and with this exception, the ages in the two groups are comparable almost all being between 20 and 40. The results in this group of primary sutures have been enhanced by the inclusion of these two children.

The type of injury Of the 14 gunshot wounds in which primary suture was performed, 12 had sufficient time to show recovery. Three of these reached a high grade M-4 or S-3 and 4 others in grade M-2 or S-1 may still improve (Fig. 5).

Twenty-seven lacerated and incised wounds, similarly treated, showed 6 good recoveries (grade M-4 or S-3) and 5 in the lower groups may improve still more.

There is no conclusive evidence from these figures of any clear superiority of primary nerve suture in lacerated and incised wounds over that performed in gunshot wounds.

Sepsis Three primary sutures were followed by gross sepsis and at operation the

came infected were eliminated. Although the results are better than when the infected cases are included, there is still a considerable proportion which have not reached a high grade of recovery.

Physical treatment. The two principal types of physical therapy which may have influenced recovery—and so far as we know only motor recovery—are passive movements to preserve joint mobility and electrical stimulation of the paralyzed muscles. The first is irrelevant since only 1 patient (P 21) had limited mobility of the joints of a degree sufficient to interfere with the function of the recovering muscles.

The influence of electrotherapy on the quality of recovery is very difficult to assess. Only those cases are available for comparison in which motor recovery is the criterion, namely ulnar and radial palsies. Fourteen out of 21 received electrotherapy but the intensity, frequency and duration of the treatment varied between such wide limits that it would be unreasonable to place too much reliance on the pooled results and in any subdivisions the numbers which were included in each instance would be statistically insignificant.

The histogram (Fig 7) shows no evidence of a significant effect of galvanism on the quality of recovery in these primary sutures.

It is clear that the factors we have discussed do not fully explain the failure of such a large proportion of primary nerve sutures to reach a high grade of recovery.

Fig. 4. Histogram showing recovery after primary and early secondary sutures of ulnar, median, and radial nerves.

ZACHARY ET AL. PRIMARY SUTURE OF NERVES

Fig. 7. Histogram showing effect of electrotherapy on recovery after primary suture of ulnar and radial nerves

CASE 23. G-42 January 19 1943 patient suffered a laceration of left wrist causing ulnar paralysis. Operation was performed within 1 hour. The ulnar nerve and several tendons were sutured. The patient was fixed in palmar flexion for 3 weeks. The patient was admitted to the Wingfield Morris Hospital. No recovery for 3 weeks. May 1943 operation was performed under general anesthesia. There was a fusiform neuroma on the ulnar nerve surrounded by dense scar tissue. Measurements were 2.5 by 1.0 by 0.8 centimeter. Stimulation produced no motor response. Resection and anastomosis were performed. Histology. The specimen was examined in transverse section at five levels. A good reunion has been separated by less than 4 millimeters and the gap along the long axis of the nerve with a very small proportion of scar tissue (contrast Case 22). But there is gross abnormality of the endoneurium of the nerve bundles in the distal trunk, for over a length of about 10 millimeters immediately below the suture line the endoneurial connective tissue is formed of a dense network of thick collagenous fibers (Fig. 8 and 9). This fibrosis is of varying severity but at almost all points in the nerve it is greatly exuberant as compared with the condition found after 4 months of uncomplicated Wallerian degeneration. This is clearly shown by the transverse section at the extreme distal end of the specimen where the nerve sheath shows the normal structure of a 4 months degenerated stump. The contrast between the two levels is well shown even at a low power of magnification (c.f. Figs. 10b and 10c). No myelinated nerve fibers are visible 3 millimeters below the suture line. Conclusion. A good reunion at the site of primary suture but with severe endoneurial collagenization in the distal trunk immediately below the suture line. This abnormality would certainly have produced a permanent bar to the regeneration of normal fibers.

CASE 24. J-41 January 5 1944 patient received laceration of the left wrist causing ulnar paralysis. Primary suture of ulnar nerve occurred within a few hours. The wrist was held in a flexed position by plaster. March 28 1944 patient was admitted to the Wingfield Morris Hospital. There was complete ulnar paralysis below the dorsal cutaneous nerve. Electromyogram of hypothenar muscles gave no evidence of reinnervation. April 19 1944 operation was performed under local anesthesia. The wound scar was continuous with that of the divided tendon of the flexor carpi ulnaris and the scar immediately around the nerve. The proximal portion measured 1.5 by 0.8 by 0.5 centimeter. The thick suture material could be seen emerging from the posterior aspect of the neuroma. Resection and anastomosis were performed. Histology. The longitudinal section through the suture line (Fig. 11) shows that the stumps are not far separated but that the path of regeneration is completely obstructed by numerous masses of suture material surrounded by granulation tissue and mature collagen. Conclusion. Reunion was prevented by fibrosis at suture material between the stumps.

CASE 25. D-43 December 29 1943 patient received a laceration of the left wrist by glass. Tourniquet was applied and removed at the hospital 35 minutes later. Immediate operation was performed and the flexor carpi ulnaris and ulnar nerve were found to be divided. Both were sutured with the wrist flexed and the position was maintained by plaster for 3 weeks. February 28 1944 patient was admitted to the Wingfield Morris Hospital. Examination revealed possibly a flicker of activity in the hypothenar muscles. The latter and the first dorsal interosseous responded to farad and sensory response. There was complete sweating operation was performed under local anesthesia. A band of scar extended down from the skin across the nerve just distal to a small neuroma. The latter measured 1.0 by 0.8 by 0.5 centimeter and the latter irregularly firm but not hard. Stimulation below the lesion gave no motor or sensory response. Histology. The proximal and distal trunks lie close together but they are not opposed to each other (Fig. 12). Thus the outgrowths from the

the Wingfield Morris Hospital. There was complete ulnar paralysis below the dorsal cutaneous nerve. Electromyogram of hypothenar muscles gave no evidence of reinnervation. April 19 1944 operation was performed under local anesthesia. The wound scar was continuous with that of the divided tendon of the flexor carpi ulnaris and the scar immediately around the nerve. The proximal portion measured 1.5 by 0.8 by 0.5 centimeter. The thick suture material could be seen emerging from the posterior aspect of the neuroma. Resection and anastomosis were performed. Histology. The longitudinal section through the suture line (Fig. 11) shows that the stumps are not far separated but that the path of regeneration is completely obstructed by numerous masses of suture material surrounded by granulation tissue and mature collagen. Conclusion. Reunion was prevented by fibrosis at suture material between the stumps.

SURGERY GYNECOLOGY AND OBSTETRICS

TABLE XL.—RATE OF JOINT EXTENSION AFTER SUTURE

Case No File No	Joint	Degree of Joint flexion	Immobilization
C 30	Elbow	Flexed	Several weeks
J 12	Wrist	Flexed	8 weeks
M 40	Wrist	Full	8 weeks
D 40	Elbow	Flexed 120°	8 weeks
J 11	Elbow	Flexed	8 weeks
K 71	Knee	Flexed 60°	25 weeks 3 weeks un- lockable

proximal and distal bundles have largely failed to unite. A few fine axons only are to be found in the nerve below the suture line.

Conclusion Poor reunion as a result of inaccurate apposition of the stumps or rotation after suture.

CASE 35. R.60 (age 62 years) May 22 1944, patient suffered laceration of the right forearm dividing median and ulnar nerves. Primary suture of nerves was done within 3 hours. September 8 1944 patient was admitted to the Wingfield-Morris Hospital. No recovery. Although recovery was not unduly delayed it was decided to explore the lesions. September 9, 1944, operation was performed under local anesthesia. The ulnar nerve was found embedded in dense scar and adherent to tendons. The neuroma measured 4.0 by 1. by 0.5 centimeter and its consistency was hard. Trial section of the site of suture revealed dense scar. Resection and resuture performed.

Histology The proximal and distal bundles at the site of suture are separated by a gap of about 7 millimeters and this is filled with dense scar tissue. Very little Schwann-tissue unites the two stumps, so that the distal nerve is poorly reinnervated, and contains only a few very fine axons.

Conclusion Very poor reunion, and separated by a gap filled with scar tissue.

CASE 4. C 63 January 3 1943 patient suffered a laceration of the right wrist. Operation was performed within 3 hours. The median nerve and several tendons were severed. The tendons were repaired and the ends of the median nerve trimmed and sutured with the wrist flexed. The wrist was immobilized in plaster for 4 weeks. March 10, 1944 patient was admitted to the Wingfield-Morris Hospital. No recovery. March 31 1944 operation was performed under general anesthesia. There was a hard neuroma measuring 2.0 by 1.0 by 0.5 centimeter. Stimulation of the nerve above the lesion produced no response in the thenar muscles. Re-section and resuture performed.

Histology The specimen consists of a fusiform neuroma with considerable epineurial scar which

increases as the site of suture is approached. Suture material is visible near the proximal and distal ends of the resected segment—an indication that some separation had probably occurred. The columns of Schwann cells at the suture line and the distal bundles are widely separated by scar tissue. In addition there is a dense collagenization of the endoneurium of the distal trunk over a length of a few millimeters below the suture line (see Case 23, Fig 8). No myelinated fibers are present in the distal nerve bundles.

Conclusion A poor union with separation and fibrosis and with abnormality of the endoneurium immediately distal to the suture line.

CASE 43. G.46 September 1943 patient received a laceration of the right wrist. At operation 13½ hours later the radial artery and superficial radial nerve, several tendons and the median nerve were found to be divided. The tendons were repaired and the median nerve and the median nerve line sutured. September 14 1943, patient was re-admitted to the Wingfield-Morris Hospital. October 13 1943, operation was performed under local anesthesia. A hard fusiform neuroma on the median nerve measured 1.4 by 1.0 by 0.5 centimeter. Stimulation below the lesion produced no sensory response and the lesion was resected and resutured.

Histology The distance between the proximal and distal bundles is small, about a millimeter. The outgrowth from the proximal bundles can be seen spreading out fanwise into a bed of granulation tissue in which the collagenous elements are disoriented and become denser as the distal bundles are approached. The outgrowth from the two stumps is not toward each other but to opposite sides of the specimen (cf Case 26) an indication of poor apposition at the time of primary suture. There are numerous foreign body giant cells well toward the center of the lesion, and clearly associated with suture material. No axons are visible in the distal bundles, which they would undoubtedly have reached after 4 weeks had the suture been successful.

Conclusion A poor union as a result of faulty apposition.

CASE 44. R.60 May 22 1944 patient received a laceration of the right forearm with division of median and ulnar nerves. Primary suture of nerves was done within 5 hours. September 8 1944, patient was admitted to the Wingfield-Morris Hospital. No recovery. September 9 1944, operation was performed under local anesthesia. The median nerve was surrounded by dense scar. The neuroma measured 2.7 by 0.6 by 1.0 centimeter and was hard. Trial section revealed only one good bundle. Re-section and resuture were performed.

Histology This gap separating the proximal and distal bundles is small, but the intermediate zone consists largely of dense masses of collagen with some aggregations of inflammatory cells. Through this scar tissue there has been only slight reunion of the stumps and the distal trunk contains no myelinated fibers. Some of the bundles contain many

Fig. 8. Case 23. Detail of the endoneurium in a nerve bundle about 8 millimeters distal to the suture line. Most of the Schwann tubes are very small in diameter and are surrounded by dense blocks of collagen. Masson, $\times 645$.

axons, but others few or none. The endoneurium of the distal bundles shows an excess of collagen immediately below the suture line.

Conclusion. A poor reunion with grossly excessive scarring between the stumps.

CASE 30. S 55. June 20, 1942, patient suffered a laceration of the right forearm. Operation was done within a few hours. The median nerve was found divided in the middle third of the forearm. It was sutured with fine silk after trimming. Plaster was applied with the elbow flexed 90 degrees and wrist flexed 45 degrees and maintained for 2 months. August 25, 1942, patient was admitted to the Wingfield Morris Hospital. Complete median paralysis below branches to long flexors. Daily physiotherapy started including galvanism to the thenar muscles. July 3, 1943, the only signs of recovery were a flicker in abductor pollicis brevis and a slight decrease in the area of analgesia. Operation was

Fig. 9. Case 23. Detail of the endoneurium in a bundle about 6 millimeters distal to the suture line. Similar to Figure 7 but the endoneurial collagen is even more dense, and the Schwann tubes hardly distinguishable. Masson, $\times 670$.

performed and a neuroma measuring 2.5 by 1.5 by 1.0 centimeter its proximal part soft but the distal portion very firm was found. Stimulation produced a motor and sensory response, but in view of the consistency of the lesion it was decided to resect and resuture.

Histology. The lesion consists of a fusiform swelling composed largely of nervous tissue. The proximal and distal bundles are connected by tissue consisting of abundantly reinnervated Schwann tubes (Fig. 13) with only slight excess of connective tissue. The distal bundles are uniformly innervated by small myelinated fibers (Fig. 15) except for half of one bundle in which myelinated fibers are deficient. Myelinated fibers are as numerous at the

Fig. 10. Case 23. Low power views of transverse sections of the nerve. a, immediately proximal to the suture line. b, 10 millimeters distal to the suture line. c, at the extreme distal end of the specimen, about 15 millimeters

distal to the suture line. a and c show normal proximal and distal nervous tissue respectively but in b the excessive endoneurial collagenization is manifested in most of the bundles by their deep staining. Masson, $\times 13$.

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 24. Case 24. The specimen in longitudinal section showing the site of suture. *P* Proximal nerve bundles, *D* distal nerve bundles. *S* remains of suture material and associated scar—many similar masses can be seen as well as those indicated by pointers. $\times 3.7$

distal level as at the proximal level above the suture line though they have not yet returned to a normal diameter (cf. Figs. 14 and 15).

Conclusion. Apparently a good reunion. The histological report casts considerable doubt on the wisdom of resection and resuture in this case, and it seemed reasonable to accept the specimen as showing good union and good reinnervation. However one year after secondary suture the patient had regained strong action in abductor pollicis brevis and there was touch and pain sensibility to the tips of the digits with no over reaction to pin prick. Thus a later secondary suture had proved superior to a primary suture in which histological examination showed an apparently successful union.

CASE 51. R 51. March 19, 1943. Patient received a gunshot wound of the left arm soft tissue wound. Radial palsy. Operation was performed 5 hours later. Extension of wound nerve almost completely severed. Small piece of bruised nerve was excised from distal end. Nerve sutured with silk. The wound closed with gauze drainage. April 7, 1943.

Fig. 25. Case 25. The specimen in longitudinal section showing the site of suture. *P* Proximal nerve bundles, *Ro* area of regeneration, *D* distal nerve bundles, *D.o* distal nerve bundles. *D* area of Schwannian and mesodermal outgrowth from the distal bundles. \times

Fig. 30. Case 30. The specimen in longitudinal section showing the site of suture. *P* Proximal nerve bundles, *S* few fragments of suture material. Nervous tissue the form of small bundles. Only a few neurolemmal areas, in continuous past the suture line. $\times 3.5$.

patient was admitted to the Wingfield Morris Hospital May 25, 1943. Operation was performed under general anesthesia. A neuroma 1.5 centimeters long, firm consistency was found. The distal trunk felt section of neuroma and 4.0 centimeters of the distal trunk were done, leaving gap of 7.0 centimeters. Suture was performed.

Histology. The longitudinal section of the specimen showed that the stumps were well apposed and reasonably close together. In the intervening area, however, there has been a considerable irregular proliferation of fibroblasts with a deposition of young collagen. This has caused a lateral diversion of some of the outgrowth of nervous tissue from both stumps with some neuroma formation (Fig. 16). Yet many regenerating fibers have reached the distal nerve distal to the suture line. The reinnervated Schwann tubes are widely separated from each other giving the appearance of gross edema. The significance of this change is uncertain but if such endoneurial edema is followed by fibroblast proliferation in the spaces it is an abnormality which would have had an adverse effect on recovery.

Conclusion. A fairly good junction but with some failure of union of the stumps and gross edema in the distal endoneurium.

Summary of histological findings. There were 5 chief histological abnormalities in these specimens sometimes more than one abnormality was evident in a single specimen.

1. Faulty apposition the proximal and distal bundles were directed toward different sides of the nerve.
2. The presence of suture material between the sutured stumps.

Fig 14. Case 30. Part of a nerve bundle in a transverse section at the proximal end of the specimen, showing the condition of the nerve fibers above the suture line. Myelin sheath stain. $\times 560$.

3 Scar between the nerve ends. The amount of scar tissue between the sutured stumps was variable but in several cases greatly excessive and clearly hindering regeneration.

4 Excessive endoneurial fibrosis was frequently noticed particularly in the distal stump immediately below the suture line. In some cases it was so excessive that satisfactory regeneration would have been impossible.

5 Separation of the sutured stumps.

The first two faults are due to poor technique in which the suturing has been inaccurate. The third and fourth are probably due to inadequate excision of the damaged nerve ends. This can hardly be classed as faulty technique since the fibrosis between and within the bundles would not be present at the time of the primary operation and we do not yet know how to recognize macroscopically the changes that will lead to excessive collagen formation within the nerve stumps. It is also possible that excessive postoperative tension on the nerve could be held responsible.

The separation of the sutured stumps may be due to unduly rapid extension of the joint which was flexed to approximate the nerve ends or else due to excessive tension at the time of operation or possibly sepsis. But of the 6 cases in which separation occurred

Fig 15. Case 30. Part of a nerve bundle in transverse section at the distal end of the specimen, showing the condition of the nerve fibers below the suture line. Myelin sheath stain. $\times 560$.

there was only 1 in which the extension of the joint had been unduly rapid (Table XI). Sepsis was present in only 2 cases and undue tension at operation must be considered to be the cause of separation in the other sutures.

DISCUSSION

The first conclusion arising out of these records is that contrary to the widely accepted view the best results of primary nerve suture do not approach nearer to perfection than the best results of early secondary suture. Indeed, considering only those cases in which there has been adequate time for recovery the proportion of good results is higher in the early secondary sutures in this series. The scales are weighted still more against the primary sutures if we take into account those in which re-exploration and

SURGERY GYNFCOLOGY AND OBSTETRICS

Fig. 4. Case 4. The specimen in longitudinal section, showing the site of suture. P Proximal nerve bundles, D distal nerve bundles, S remains of suture material and associated scar—many similar masses can be seen as well as those indicated by pointers. X-37

distal level as at the proximal level above the suture line, though they have not yet returned to a normal diameter (cf. Figs. 4 and 15).

Conclusion Apparently a good reunion. The histological report cast considerable doubt on the wisdom of resect on and resuture in this case, and it seemed reasonable to accept the specimen as showing good union and good reinnervation. However one year after secondary suture the patient had regained strong action in abductor pollicis brevis and there was touch and pain sensibility to the tips of the digits with no over reaction to pin prick. Thus a later secondary suture had proved superior to a primary suture in which histological examination showed an apparently successful union.

CASE 51: R-31 March 19 1943 patient received a gunshot wound of the left arm soft tissue wound. Radial palsy. Operation was performed 5 hours later excision of wound, nerve almost completely severed. Small piece of bruised nerve was resected from distal end. Nerve sutured with silk. The wound closed with gauze drain. April 7 1943

Fig. 6. Case 59. The specimen in longitudinal section, showing the site of suture. P Proximal nerve bundles, D distal nerve bundles, S a few fragments of suture material. Nervous tissue, in the form of small bundles with only a few neurolemmal areas, is continuous past the suture line. X-35

patient was admitted to the Wingfield Morris Hospital, May 25 1943 operation was performed under general anesthesia. A neuroma 15 centimeters long firm consistency was found. The distal trunk felt firm for 4 centimeters distal to the neuroma. Resection of neuroma and 4.0 centimeters of the distal trunk were done leaving gap of 7.0 centimeters. Suture was performed.

Histology The longitudinal section of the specimen showed that the stumps were well apposed and reasonably close together. In the intervening area however there has been a considerable irregular proliferation of fibroblasts with a deposition of young collagen this has caused a lateral diversion of some of the outgrowth of nervous tissue from both stumps with some neuroma formation (Fig. 16). Yet many regenerating fibers have reached the distal nerve distal to the suture line the reinnervated Schwann tubes are widely separated from each other, giving the appearance of gross edema. The significance of this change is uncertain, but if such endoneurial edema is followed by fibroblast proliferation in the spaces it is an abnormality which would have had an adverse effect on recovery.

Conclusion A fairly good junction but with some failure of union of the stumps and gross edema in the distal endoneurium.

b Summary of histological findings There were 5 chief histological abnormalities in the specimens sometimes more than one at a time. 1 Faulty apposition in a single specimen distal bundles were directed toward different sides of the nerve. 2 The presence of suture material between the sutured stumps.

Fig. 14. Case 39. Part of a nerve bundle in a transverse section at the proximal end of the specimen showing the condition of the nerve fibers above the suture line. Myelin sheath stain. $\times 560$.

Fig. 15. Case 39. Part of a nerve bundle in transverse section at the distal end of the specimen showing the condition of the nerve fibers below the suture line. Myelin sheath stain. $\times 560$.

3 Scar between the nerve ends. The amount of scar tissue between the sutured stumps was variable but in several cases greatly excessive and clearly hindering regeneration.

4 Excessive endoneurial fibrosis was frequently noticed particularly in the distal stump immediately below the suture line. In some cases it was so excessive that satisfactory regeneration would have been impossible.

5 Separation of the sutured stumps.

The first two faults are due to poor technique in which the suturing has been inaccurate. The third and fourth are probably due to inadequate excision of the damaged nerve ends. This can hardly be classed as faulty technique since the fibrosis between and within the bundles would not be present at the time of the primary operation and we do not yet know how to recognize macroscopically the changes that will lead to excessive collagen formation within the nerve stumps. It is also possible that excessive postoperative tension on the nerve could be held responsible.

The separation of the sutured stumps may be due to unduly rapid extension of the joint which was flexed to approximate the nerve ends or else due to excessive tension at the time of operation or possibly sepsis. But of the 6 cases in which separation occurred

there was only 1 in which the extension of the joint had been unduly rapid (Table VI). Sepsis was present in only 2 cases and undue tension at operation must be considered to be the cause of separation in the other sutures.

DISCUSSION

The first conclusion arising out of these records is that contrary to the widely accepted view the best results of primary nerve suture do not approach nearer to perfection than the best results of early secondary suture. Indeed considering only those cases in which there has been adequate time for recovery the proportion of good results is higher in the early secondary sutures in this series. The scales are weighted still more against the primary sutures if we take into account those in which re-exploration and

Fig. 7 Histogram showing delay before admission to nerve injury center after primary nerve suture.

resuture were necessary. What is the explanation for the failure of so many primary sutures to reach the expected high standard?

It has been all too readily assumed in the past that if infection can be avoided after primary nerve suture the result should be good. Although in a few of the cases recorded above sepsis may have been an adverse factor there are many in which the wound healed without sepsis and yet the recovery was poor.

We have no evidence that the results in this group of primary sutures have been unfavorably influenced by lack of physical therapy. Indeed, an unduly favorable effect has probably resulted from the inclusion of two children in the series. We must, therefore, assume that the quality of surgical repair which is possible at the time of the primary operation is a factor of considerable importance. The standard of surgery depends on the experience of the surgeon, the facilities available for good surgery and the condition of the injured tissues.

It might be suggested that it is unfair to compare primary sutures performed by surgeons of all types with secondary sutures performed at a nerve injury center by men experienced in nerve repair. However, many of the primary sutures which have failed were performed by experienced surgeons. More over after one of the primary sutures under taken at this nerve center a case in which there were no complicating factors, the results were not good. Furthermore, the wound treatment in peace or war is not usually performed by senior surgeons and we think it likely that we have in this series a fairly representative selection of the work of

those surgeons who are normally faced with the problem of primary nerve suture. It must be noted that we have excluded from this series three examples of gross error at the time of primary nerve suture when a nerve was sutured to a divided tendon.

Nearly all the primary sutures were undertaken at hospitals in this country in which the facilities for such emergency work are adequate.

In our opinion the chief adverse factor in primary suture is the difficulty in recognizing how much of the nerve has been damaged on each side of the site of division, with the result that resection is often inadequate. On the other hand if the resection is satisfactory there is the risk of excessive tension at the site of suture, since extensive mobilization of the nerve is never performed in a fresh wound. After 3 or 4 weeks the intraneural connective tissue changes are sufficiently obvious to indicate the amount of nerve to be resected, and there is the additional benefit of thickened nerve sheath which facilitates suture and makes the suture line more stable; the epineural stitches are less likely to pull through such a sheath than they would through that of a freshly divided nerve.

One further objection to the selection of cases in this series might be that only those primary sutures which were not progressing favorably would be sent to a nerve injury center. Many good results would thereby be missed. There are two answers to this objection first by arrangement with the medical departments of the three services, all cases of peripheral nerve injury are referred to appropriate centers. Second it is seldom possible to be sure within 6 months of the

date of suture whether the final result is likely to be good or not. We have ourselves found this difficulty even after sutures at the level of the wrist. Thirty six out of the total of 49 patients were referred to us earlier than 6 months after injury (Fig. 17) and it cannot, therefore, be accepted that we have had an undue proportion of those in whom the result was known to be poor.

CONCLUSION

The results set out in this paper raise important questions of policy in the primary treatment of divided nerves. In the usual civil or industrial laceration where one can expect wound healing within a few weeks primary suture may give a good result, but one can be more certain of a high grade of recovery after an early secondary suture. However there is nothing to be lost and indeed a great deal to be gained by approximating the ends of the divided nerve to prevent retraction. When secondary suture is performed in a few weeks the length of nerve to be resected will probably be short the suture can be performed with precision and without tension and the prospects of recovery will be good. If deliberate primary suture has been performed the patient should be watched carefully for early signs of recovery and if they are lacking or progress appears to be unduly slow re-exploration should be undertaken without delay and further resection and resuture considered.

In war wounds the local damage to the nerve ends is likely to be more extensive and the chances of performing an adequate excision of damaged nerve trunk and accurate epineural suture at the primary operation are not so good. An early secondary suture is more reliable. Here again primary approximation of the nerve ends is important and with adequate wound surgery and the latest adjuncts to prevent sepsis and encourage wound healing the secondary operation should be possible within a few weeks or at most a few months. Although we have arbitrarily chosen a limit of 6 months for

early secondary sutures we are convinced that, even within this period, the earlier the suture is undertaken the better.

We can sum up our views as follows. Formal nerve suture should be undertaken at the earliest moment when it is possible to recognize the extent of damage to the nerve excise the injured segment and bring together the mobilized nerve ends without the prospect of undue postoperative tension.

SUMMARY

1 The results of 55 primary nerve sutures are presented and compared with results of a series of early secondary sutures.

2 There was a higher proportion of poor recoveries and a lower proportion of good recoveries after primary suture.

3 Sepsis was not the chief adverse factor involved.

4 The histological examination of the site of primary suture in 16 cases indicated that the chief faults were poor technique inadequate resection of the damaged nerve ends and excessive postoperative tension.

5 There is a better prospect of a good recovery after an early secondary suture than after primary suture.

6 Primary approximation of the divided nerve stumps is always advisable.

A CLINICAL AND PATHOLOGIC STUDY OF THE KIDNEY IN PATIENTS WITH THERMAL BURNS

W. E. GOODPASTOR, M.D., S. M. LEVENSON, M.D., H. J. TAGNON, M.D.,
C. C. LUND, M.D., F.A.C.S., F. H. L. TAYLOR, Ph.D., Boston, Massachusetts

IMPAIRMENT of kidney function as evidenced by persistent oliguria and elevation of the nonprotein nitrogen in the blood is a frequent early complication in the course of patients with severe thermal burns. (9,34) This syndrome is often accompanied by albuminuria and urinary casts (34). A few descriptions of the morphology of the kidneys in patients dying with burns have been published (9,10,23,34) the most consistent findings being the following—on microscopic examination the glomeruli are usually normal while the tubules show varying degrees of necrosis affecting principally the convoluted part. Pigmented casts have also been observed in the tubules. These have been considered to be hemoglobin casts although direct proof of this is lacking. Some support to this conception of the nature of the casts is lent by the occurrence of hemoglobin in the blood and urine of severely burned patients (23). In none of these reports however has there been an attempt made to correlate the clinical and pathologic findings. Such a study based on 47 patients with fatal thermal burns admitted to the Boston City Hospital during the period from November 1942 to July 1944 is presented here. Additional data on patients who were admitted and survived during the same period will be presented elsewhere.

METHODS

In the following study the area of burn was estimated by the method of Lund and Brown

der. The depth of burn is described according to the new method of Converse and Robb-Smith. They classify burns by name instead of number using the terms epidermal for so called first degree burns, dermal and deep dermal for second degree and deep for third degree. The area of epidermal burn was disregarded. The extent of the deep burn cannot be determined with accuracy in patients who survive for only a few days. For this reason the extent of deep burn in such patients can only be estimated. Associated respiratory tract injury was graded from 0 to 4, depending upon the extent of injury to the respiratory tract found at autopsy.

The local treatment of the burns varied. During 1942 triple dye and tannic acid-silver nitrate were most frequently used, while during 1943 and 1944 the most frequent methods were pressure dressings or casts, dry or with a bland ointment. Morphine was usually given two or three times in the first 36 hours, in doses of $\frac{1}{4}$ grain for adults and correspondingly smaller doses for children. In a small number of patients phenobarbital or pentobarbital were used for sedation. Most patients with burns involving more than 10 per cent of the body surface received intravenous infusions of citrated plasma or serum. The plasma contained dextrose in amounts varying from 10 to 17 grams for each unit of 250 cubic centimeters. Some contained merthiolate in a final concentration of 1:10,000 as a preservative. Many patients received transfusions of type specific citrated whole blood. A small number of patients received intravenous injections of a 25 per cent solution of human albumin. This also contained an organic mercurial 1:10,000 as a preservative. Sodium lactate was given intravenously to some patients in the form of a molar aqueous solution and others were given sodium bicarbonate by the oral and intravenous routes.

From the M. I. I. Institute of Pathology, the Thorndike Memorial Laboratory, Second and Fourth Medical Clinics (Harvard) and the Burns Department of the Surgical Services, Boston City Hospital, and the Departments of Medicine and Surgery, Harvard Medical School, Boston. The work described in this paper was done, in part, under contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and Harvard University.

Fig. 1. Case 16. Note pale swollen cortex and contrastingly dark medulla with dark lines converging toward papillae. These lines in fresh tissue are black and histologically prove to be tubules containing blood pigment casts.

Intravenous glucose and isotonic salt solutions were also given to most of the patients.

In the evaluation of kidney function the following signs were considered to constitute evidence of lasting impairment—persistent azotemia with a level of nonprotein nitrogen exceeding 40 milligrams per 100 cubic centimeters of blood and oliguria or anuria persisting beyond the period of shock. Periods of transient azotemia and oliguria occurring only during the period of shock or terminally or associated primarily with heart failure were not considered evidence of lasting renal dysfunction due to the burn. The plasma nonprotein nitrogen, total protein, and albumin determinations were carried out by the routine methods as given by Peters and Van Slyke. In patients receiving sulfonamides (chiefly sulfadiazine) the blood levels of the drug were determined at regular intervals. Hemoglobinuria was detected by examination of the supernatant plasma in the hematocrit tube. The icterus index was estimated by the method of Murphy.

Hemoglobinuria was detected by the red or dark red appearance of the urine in the absence of gross hematuria. In most cases the diagnosis was confirmed by a guaiac or benzidine test. In some cases the qualitative

reaction for detection of hemosiderin with ammonium sulfide was carried out. The urine was usually tested for acidity or alkalinity by litmus paper but occasionally more accurate estimation was made with nitrazine paper.

Shock was recognized by the usual clinical criteria of fall in blood pressure, rapid thready pulse, clammy extremities. An attempt was made to grade the severity of shock according to intensity and duration. The following criteria and qualifications were used for grading: 0 patients who were never in shock; 1 patients who were once in shock for a period not exceeding 1 hour; 2 patients who were in shock from 1 to 4 hours; 3 patients who were in shock for longer than 4 hours or were in shock on more than one occasion. This last group includes also all patients who died in shock.

Morphologic examination of the kidney was done on sections fixed with Zenker's fluid and formalin and stained with phloxine, methylene blue, Lee-Brown modification of Mallory's aniline blue stain, sudan IV for fat, and a modified van Gieson stain for hemoglobin described by Dunn and Thompson. With this last method hemoglobin casts in the kidney stain varying shades of green. In our

sections casts or portions of casts composed of desquamated tubule cell debris stained hematoxylin. Benzidine methods of demonstrating unsaturated globin, possibly because of long fixation in formalin.

A number of patients who were burned in the Cocoanut Grove fire are included in this report. In some of these cases it was impossible to secure all the desired data. However no patient in whom the essential clinical and laboratory data are lacking has been included.

OBSERVATIONS

Renal Morphological Changes

Twenty of the 47 patients showed definite morphologic changes in the kidney at autopsy. In 2 cases the renal lesion was acute pyelonephritis, entirely different from the lesions in the 18 other patients. In these latter patients the changes were all similar and consisted chiefly of the presence of tubular casts and degeneration and necrosis of the tubular epithelium (Figs. 1 to 7).

1 *Tubular casts* Tubular casts were found in all 18 cases and were made up of (1) pigment, and (2) desquamated epithelial cells. A maximum of 50 per low power field were found (Fig. 2). Casts composed largely or exclusively of pigment were most numerous. Casts composed entirely of epithelial cells were rare. Morphologically the pigment casts had a fine or moderately coarsely granular structure (Fig. 3). Most often the granules were approximately the size of red blood cells, or smaller. Large elongated crystal like green or blue cast particles were

sometimes found. The color with phloxine methylene blue stain varied from red to orange, brown green and blue. The blue color was most frequent although all the other colors usually could be seen in a single section. A positive staining reaction for hemoglobin in the casts was observed in all 17 cases in which this procedure was carried out. These casts were observed exclusively in the ascending and descending portions of the loops of Henle and in the collecting tubules. The greatest number was found in the medulla (Fig. 2) although some could also be seen in the cortex. Identification of the tubule involved was impossible in some instances because of presence of degenerated epithelium adjacent to a cast. The epithelial casts were made up of necrotic tubular epithelial cells, although pigment particles were usually present also (Fig. 6). These casts usually were acidophilic with phloxine methylene blue stain. When stained by the method of Dunn and Thompson for hemoglobin the cell debris stained red and the particles of pigment when present green. The staining reaction and the very fine granularity of the cell debris were similar to that of the cytoplasm of easily identifiable intact degenerated epithelial cells. In an occasional cast infiltrating monocytes and polymorphonuclear leucocytes were seen. Fibrin deposits in tubules were small and rare.

2 *Degeneration and necrosis of renal tubules* This change was found in two sites, i.e. in convoluted tubules and about casts lying within distal portions of the tubules. The degeneration and necrosis in these two sites seem to be distinctly different.

Necrosis and degeneration of convoluted tubules was found in 7 of the 18 patients. The tubules were swollen pale and granular. In some instances the cytoplasm was vacuolated in others the cells were partially or completely disintegrated so that individual cells could not be defined and the lumens of the tubules were filled with disintegrated cells (Figs. 4-5-7). The nuclei were often pyknotic or absent. There was no correlation between the number of pigment casts and the extent of tubular necrosis. In each instance the kidneys described as having tubule necrosis or degeneration also showed indirect evidence of

Fig. 4. Case 4. A large mitotic figure in a regenerating convoluted tubule is shown in the central part of the field. The tubule at the right of the field shows almost complete loss of epithelium with amorphous debris filling the lumen.

Fig. 5. Case 18. Casts here are composed of desquamated cell debris and blood pigment granules. The cell debris components are the large, rounded, dark bodies (red in phloxine-methylene blue sections and in sections stained for hemoglobin). Blood pigment particles are smaller and less dark (brown green or blue in phloxine-methylene blue sections and giving a positive stain for hemoglobin). Note also local damage to tubules containing the casts.

Fig. 6. Case 9. Convoluted tubules showing degeneration and regeneration. In the center is a tubule with flat, recently regenerated epithelium. There is a mitotic figure at the extreme left of this tubule.

the antemortem nature of the changes by the presence of one or more of the following—regenerating epithelium, mitotic figures indicative of tubular regeneration and casts in the distal portion of the tubules composed of desquamated necrotic epithelial cells.

Tubular necrosis adjacent to casts were seen in 12 cases. The necrosis was limited to the cells surrounding casts. The cells were not swollen, pale or granular but were deeply eosinophilic. Nuclei were pyknotic or absent. In many instances the cells had become separated from the basement membrane and incorporated into the cast. About some casts no cells were seen and only the basement membrane of the tubules remained.

3 Regeneration of epithelium Regenerating epithelium was found in 7 cases. Its presence is indicative of repair of tubular necrosis. In some cases necrosis was demonstrable along with regeneration. In others, actual necrotic cells were no longer present.

Regenerating epithelial cells in the presence of necrotic cells were flat and basophilic lying against the basement membrane. In contrast, the eosinophilic, pale, granular necrotic cells often overlaid the regenerating cells (Figs. 4, 5). Mitotic figures were usually not numerous (Figs. 4, 5, 7). Cells with mitotic figures were usually large cells which protruded prominently into the lumen (Fig. 5). In tubules which were composed entirely of recently regenerated epithelium and from which the necrotic cells had disappeared, the lumen appeared large because of the flat lining epithelium (Fig. 7). Mitotic figures in these less actively regenerating tubules were fewer.

4 Gross pathological changes In contrast to the microscopic examination gross examination of the kidney revealed abnormalities in only 5 cases. In 3 cases the medulla had a dark red appearance and presented prominent black, brown, or purple-red streaks converging toward the papillae. The dark streaks in the pyramids correspond to the tubules filled with pigment casts. In 4 cases the cortex and the zone of the medulla included between the pyramids were definitely paler and more swollen than normal (Fig. 1). This appearance was considered due to the tubular degeneration. In 2 cases, the kidney

weights were significantly higher than normal whereas in all other cases the weight of the kidneys approximated the upper limit of the normal value or was only slightly increased. In 2 cases unidentified orange crystals were seen. Small areas of hemorrhage were seen in the mucosa of the pelvis in 4 cases. In 1 case a similar area of hemorrhage was observed beneath the mucosa of the ureter.

5 Classification of the patients according to the morphological changes For the purpose of analysis, the 47 patients are divided into two groups on the basis of the autopsy findings. Group 1 comprises those in whom definite morphologic abnormalities were found in the kidneys while Group 2 is made up of those in whom no definite anatomical changes were found in the kidneys. Group 1 is composed of 20 patients and group 2 of 27 patients. Three patients in group 2 who died within 6 hours after injury are considered separately since they differed markedly from the others in extent of deep burn, severity of shock, clinical course, and early death. Two patients in group 1 are also considered apart since the morphologic abnormalities observed in their kidneys were probably not directly related to the burn. In both of these patients the renal lesion was that of acute pyelonephritis and was different from the renal lesions observed in the other 28 cases in group 1.

In the following discussion, the patients in group 1 (with the exception of 2 patients) will be contrasted with the 24 patients in group 2 who survived longer than 6 hours following injury.

Renal Function

A striking contrast between the two groups appears when the renal function is considered. The elevation of nonprotein nitrogen was higher in group 1 than in group 2. Two group 1 cases had nonprotein nitrogen levels above 150 milligrams per 100 cubic centimeters and 7 others had levels above 80. In group 2 only 3 patients had levels as high as 80. The high elevation was more constant in group 1 than in group 2. Sixteen out of 17 of the former cases on which data are available had an elevated level commencing shortly after injury and persisting to death. Among the

group 2 cases, 15 of the 24 patients had an elevation at any time and 3 of these elevations occurred late in the course. In most of the remaining group 2 patients the elevation decreased to normal before death after an early elevation.

Oliguria of a persistent nature was present in 7 of 11 patients of group 1 surviving longer than 2 days. All patients in this group who died within 48 hours also had oliguria. In contrast oliguria was observed in 6 patients of group 2 and in 5 of them it was limited to the period of shock. In the sixth patient the oliguria was associated with cardiac failure.

Examination of the incomplete data on specific gravity of the urine does not show a clear correlation between the amount of retention of nonprotein nitrogen in the blood and the ability of the kidney to concentrate or dilute urine.

A comparison of the amounts of nitrogen excreted in the urine by the patients of the two groups is difficult because determinations of daily urinary nitrogen were not carried out in all cases and because of the differences in time of survival after injury between the two groups of patients. However the available data suggest that there was, on the average, a higher output of urinary nitrogen in patients of group 2 than in patients of group 1. This is rendered more significant by the fact described above that the blood nonprotein nitrogen level was more elevated in group 1 than in group 2. Data on urinary nitrogen as compared to the blood levels of nonprotein nitrogen in 2 of our cases illustrate this point.

Urine reaction: Eleven of 13 patients in group 1 on whom the initial reaction of the urine was tested had acid urine. In the 2 other cases, it was neutral. Two had alkaline urines subsequently in the first 24 hours. In group 2 the initial reaction of the urine was tested in 13 patients and found acid in all except 3. It was alkaline in 2 cases and neutral in the third. Subsequent samples of urine were acid in most cases.

Other findings in the urine. Granular and hyaline casts were found in the urine of 9 patients in group 1 and 4 in group 2. Protein was present in significant amounts in the

urine of 15 patients in group 1 and in 12 patients in group 2. Significant numbers of red and white cells were found occasionally in the urine of 13 patients and repeatedly in the urine of 5 patients in group 1. Thirteen patients in group 2 had white and red blood cells in the urine on one or more occasions. Peripheral edema was observed in 8 cases in group 1 and in 4 cases in group 2.

Age Sex Surface Treatment and Fever

There were no essential differences between the patients in both groups in regard to age sex and surface treatment. The ages varied from 1 year to 78 years. The sexes were equally divided. Dry gauze or petroleum jelly pressure dressings were the most frequent form of surface dressing. Four patients in each group were treated with triple dye. Four patients in group 1 and 2 in group 2 were treated by the application of tannic acid and silver nitrate. All patients had fever at some time during the course of their illness. There was no significant difference between the two groups as far as number of patients with fever and intensity of the pyrexia are concerned.

Other Observations

Hypoproteinemia Eleven patients in group 1 and 17 in group 2 had hypoproteinemia at some time during their hospital course. In almost all the fraction of the plasma protein most lowered was the albumin fraction.

Surface area burned. In general the patients in group 1 had more extensive burns than did the patients in group 2. In group 1 10 patients had 50 per cent or more of the body surface burned while only 3 patients in group 2 had burns of this extent. This marked contrast is also apparent when the extent of deep burn is compared in both groups. Thus, in 12 patients in group 1 the extent of deep burn was 35 per cent or greater of the body surface while in only 4 patients of group 2 was the deep burn of this extent. One patient in group 1 had a conspicuously small burn.

Respiratory damage. Many patients in each group suffered respiratory damage from inhalation of hot air and smoke. Very severe grade 4 respiratory damage was sustained by 4 patients in each group.

Hemoglobinemia and hemoglobinuria Hemoglobinemia was observed in all cases of group 1 in whom the determination was done and lasted from 1 to 4 days after the burn. It was observed to a lesser degree in 14 patients in group 2. Six patients in this group did not have hemoglobinemia. Twelve of the 16 patients in group 1 on whom data are available had hemoglobinuria while only 1 patient in group 2 had hemoglobinuria. Hemoglobin casts were seen in the urine of 3 patients in group 1 and in none in group 2.

Hemoconcentration During the first 24 hours hemoconcentration was observed in twelve patients in group 1 and in 16 in group 2.

Shock Sixteen patients in group 1 and 12 patients in group 2 had clinical shock at some time during the first 36 hours. However the severity and duration of shock was greater in group 1 than in group 2. Grade 3 shock was observed in 11 cases in group 1 and in only 3 cases in group 2. It should be pointed out, however, that 2 patients in group 1 had no shock and 1 had mild shock.

Plasma and serum The quantity of plasma and serum given was, on the average, higher in patients of group 1 than in patients of group 2; the average in group 1 being 2.9 liters, the average in group 2 1.8 liters in the first 48 hours. Most of the plasma was given in the first 24 hours.

Albumin In the form of a 25 per cent solution was given during the first 48 hours to 5 patients in group 1 and to 4 patients in group 2. It was given later to 3 group 1 patients and to 1 group 2 patient.

Mercury The plasma serum and albumin used early in the study contained an organic mercurial preservative and some of the patients received enough plasma in relation to their body weight in the first 24 hours to raise the question of mercury toxicity. However 7 patients in group 1 received fluids without mercury.

Physiological saline In variable quantities was given parenterally to most patients in both groups. The average amount given during the first 48 hours was 1.9 liters in group 1 and 1.5 liters in group 2.

Parenteral glucose solution 5 or 10 per cent was given to practically all patients in both

groups. The average amount given in the first 48 hours was 1.9 liters in each group.

Blood transfusions Eight patients in group 1 and 10 patients in group 2 received type specific blood transfusions during their course. There was no evidence of a hemolytic transfusion reaction in any patient. Furthermore, there were 10 patients in group 1 who did not receive blood.

Drug therapy Six patients in group 1 and 18 in group 2 received sulfadruugs. This was sulfadiazine in most cases, 3 patients receiving sulfathiazole. Drug levels in the blood were markedly elevated in 1 case and moderately elevated in 2 cases in group 1. They were moderately elevated in 4 cases in group 2.

Sulfadruug crystals in the urine were found repeatedly in 1 case and on 1 occasion in one other case in group 1. They were found repeatedly in 3 cases in group 2. In no instance was this accompanied by significant hematuria. There were 7 patients in group 1 who received neither blood transfusions nor sulfonamides, and there were 2 patients who received neither blood transfusions, sulfonamides nor mercury.

Sodium lactate or bicarbonate was given on entry to 12 patients of group 2 and to 14 patients in group 2.

Diuretics Aminophylline, 50 per cent glucose solution or both were given intravenously to a number of patients in each group. The glucose solution was given in 4 cases and aminophylline in 21 cases, 12 in group 1 and 9 in group 2. In most cases the aminophylline was given for bronchial spasm and not as a diuretic. There was no evidence that the hypertonic glucose solution or the aminophylline had any significant diuretic effect in these cases. Albumin was given for possible diuretic action to 3 group 1 patients. In 1 of these it seemed to have a definite diuretic action (see Case 4 report) while in the 2 others no effect was observed (see Case 2 report).

Complications and time of death. The most common complication encountered in the 2 groups of patients were of a pulmonary nature. Pneumonia, bronchopneumonia, and pulmonary congestion occurred in about one-half of the patients in each group. Other compli-

cations were atelectasis of the lung in 2 cases pyrogenic plasma reaction in 2 cases, the latter having received grossly contaminated plasma acute hemorrhagic cystitis in 5 cases cerebral edema in 3 cases, and central necrosis of the liver in 1 case

On the whole the patients in group 1 died earlier than did the patients in group 2 The cause of death was variable In many cases the injury to the respiratory tract was the chief cause of death In some death was due to the complications noted above (chiefly pneumonia) but in some cases it was impossible to state what the patient died of more specifically than extensive burns Two patients in group 1 died of shock due to burn In only 2 cases could kidney failure be considered the chief cause of death

Patients with acute pyelonephritis As was stated before, 2 patients in group 1 are considered separately since although the kidneys in these 2 patients were abnormal morphologically the anatomical lesion was quite different from that observed in the 18 other patients in group 1 The renal lesion in these 2 patients was that of acute pyelonephritis. Both were in shock and had hemoglobinemia on admission Patient 16 in addition had hemoglobinuria Patient 3 had been on constant bladder drainage from the time of admission to death.

Patients in group 2 who died within 6 hours after burn Three patients in group 2 are also considered separately since they differed so much clinically from the remaining patients in this group All 3 had extensive deep burns and respiratory tract injury They were all in profound shock and had marked hemoglobinemia One was completely anuric while the 2 others excreted a very small quantity of acid urine containing hemoglobin The non-protein nitrogen level in the blood was elevated on admission in 1 patient and normal in 2 patients. All 3 patients died within 6 hours after admission 2 (Cases 21, 23) of shock and 1 (Case 22) of asphyxiation None showed any renal changes at autopsy

CASE REPORTS

CASE 20 Extensive deep burns hemoglobinuria shock oliguria azotemia and marked renal changes at

autopsy This 9 year old boy with a noncontributory past history was admitted shortly after receiving deep flame burns of almost his entire body Examination revealed a well developed and well nourished boy in moderate distress The total burned area was about 90 per cent Most of the areas appeared to be deep The skin was hard leathery and brown with very little external ooze. Areas were clean The chest was clear throughout The pulse was 100 of good quality blood pressure 110/70 and the respirations 20.

Under morphine sedation $\frac{1}{4}$ grain, petrolatum pressure dressings were applied to all areas except the abdomen which was treated with triple dye By the end of the dressing the patient had received 200 cubic centimeters of plasma containing 20 cubic centimeters of molar lactate He was definitely in shock at this time The pulse was very rapid and thready the feet hands and face (which were the only exposed areas) were cyanotic and cold Plasma was forced in by syringe, 450 cubic centimeters being given in 10 minutes. There was immediate improvement in the circulation He was catheterized at this time and a small amount of dark brown acid urine was obtained He was left on constant bladder drainage. He was given sodium bicarbonate one half gram by mouth During the next 12 hours the patient received about 2500 to 3000 cubic centimeters more of plasma and 20 cubic centimeters of molar sodium lactate He took only a small amount of water by mouth and vomited as soon as any fluid was taken His pulse varied from 100 to 140 The blood pressure could not be taken because the extremities were in dressings The temperature rose to 104 degrees rectally at 14 hours and exposed areas were sponged with cold alcohol He became stupor and the pulse was barely perceptible. Five hundred cubic centimeters of plasma and $\frac{1}{2}$ gram of sodium bicarbonate was given rapidly in 10 minutes by syringe with definite improvement in the quality of the pulse Shortly thereafter he began having generalized twitchings and clonic movements each convulsive episode lasting about 5 minutes. Lu minimal in 2 grain doses was given intramuscularly The temperature rose to 107 degrees and pulse to 150 and was weak. He remained comatose and died 36 hours after entry He had received a total of 4800 cubic centimeters of plasma intravenously His total output was 90 cubic centimeters of very dark brown urine

Laboratory data The hemoglobin total protein and nonprotein nitrogen data are given in Chart 1 and nonprotein nitrogen data are given in Chart 1 There was moderate hemoconcentration on entry which was corrected by the plasma infusions The plasma protein concentration remained within normal range The nonprotein nitrogen rose rapidly from a high normal value to over 100 milligrams. Hemoglobinemia was marked Analysis of the urine specimens revealed a dark brown acid urine of specific gravity 1.030 with no acetone, bile or sugar It continued to be dark brown or black. The amount of proteinuria increased progressively from

Chart

a slight trace to a very heavy trace. The sediment revealed granular casts and γ t. to red blood cells. The benadine and hemosiderin stains were positive.

Autopsy findings. B rns covered 90 per cent of the body surface and were chiefly deep. The lungs were congested and edematous with partial atelectasis of the lower lobes. The combined weight of the kidneys was 160 grams. The cut surface revealed a slightly redder than normal cortex and medulla with minute red streakings converging at the papillae. Microscopic examination revealed that the glomerular spaces contained dark blue granular precipitate. The same precipitate was found in most tubules. There was no modification of the basement membrane of the tufts and no cellular infiltration or endothelial or epithelial hyperplasia. The tubules contained numerous pigment casts. Fifty casts were counted in a single low power field (100X) in the medulla. The casts were found in the descending limbs of Henle's loop and collecting tubules. Most of the casts were composed of red granules. Some, however, were brown others blue. The particles ranged from fine granules to larger round masses. Most cast particles gave a positive stain (green) for hemoglobin. Mononuclear cells with eosinophilic cytoplasm and pyknotic nuclei were encountered occasionally within the casts. The cytoplasm of these cells stained red with hemoglobin stain. The convoluted tubular changes were marked and except for the absence of regenerating epithelium were identical with that seen in the kidneys of Case 12. There were areas where the nuclei were

completely missing and the cells were granular and had filled the tubular lumen with amorphous masses of cytoplasm. There did not appear to be any interstitial edema. There was no leukocytic infiltration. There was no congestion of interstitial vessels.

CASE 1. *Minimal surface burn was followed by respiratory tract injury, no shock, anemia and renal changes at autopsy.* This 43 year old woman received burns at the Coconut Grove fire. She had inhaled a considerable amount of hot smoke and had lost consciousness. The past history was not obtained. Examination revealed a fairly well developed and well nourished woman. She was unconscious. She had marked stridor, dyspnea, and cyanosis. The only external burn was a small area on her nose. The pulse was rapid. During the first 24 hours she received 1000 cubic centimeters of plasma, 1500 cubic centimeters of saline and 1000 cubic centimeters of glucose in water. No data are available as to the urine output on the first day. On the second day 500 cubic centimeters of dark urine was passed and on the third day 300 cubic centimeters. At the end of 9 hours because of increasing respiratory distress, a tracheotomy was performed. The respirations improved markedly for a brief period. On the third day sulfadiazine was started. The respirations continued to be labored with coarse rales throughout both lung fields. The patient died on the fourth day following a sudden increase in respiratory distress.

Laboratory data. On the second day the hemoglobin was 90 per cent and the nonprotein nitrogen

Chart 2

Chart 3

was 94 milligrams per 100 cubic centimeters of plasma. The urine was dark in color with a slight trace of albumin and no sugar or acetone. There were 0-5 white blood cells and no casts.

Autopsy findings. The following were noted: a burn dermal, of nose acute laryngo tracheobronchitis (inhalation) congestion of the spleen and liver, bronchopneumonia and edema of the lungs. The kidneys together weighed 310 grams. The pale gray pink cut surface of the cortex was clearly demarcated from the deeper stained red-blue pyramids. Microscopic revealed glomerular capsular spaces contained a moderately heavy precipitate. The same precipitate was found also in all tubules. Otherwise there was no glomerular change. The capillaries contained blood, no thrombi were present. There was no modification of the basement membrane. There was no endothelial or epithelial cell hyperplasia or inflammatory cell infiltration. The tubules contained casts and showed some damage to the tubular epithelium. The casts were found in the tubules of the medulla and less often in tubules of the cortex. The epithelium was so modified in the portions containing casts that it was not always possible to identify the type of tubule. Collecting tubules and ascending limbs of Henle's loop were recognized in a few instances. The casts were for the most part composed of densely packed fine basophilic granules. There was a brown to red color to some casts. Part of some casts were pale blue and homogeneously smooth. An occasional cast was composed of larger bright red globular particles. With hemoglobin stains there were many casts of green particles and others of red. Recognizable desquamated cells presented red cytoplasm and pyknotic nuclei. It should be mentioned that here, as in other cases the nonpigment casts stained red and were cell debris in origin. Tubular necrosis was slight and seen most prominently in those portions containing casts. In places only the basement membrane remained elsewhere the epithelium was reduced to very flat cells. The tubular cells surrounding casts were flattened the cytoplasm deeply eosinophilic and the nuclei pyknotic others had fallen away from the basement membrane seeming to become part of the cast. The convoluted tubules gave the impression of being dilated, there being a considerably greater sized lumen than is usual. The cells were low and granular, and many cells contained no nuclei. Regenerating epithelium growing beneath degenerated cells was seen only rarely. A very rare mitotic figure was found. There was no cellular infiltration of interstitial tissue and no scars. Capsules, arterioles and pelves were not remarkable.

CASE 9. Extensive deep burn shock hemoglobinuria azotemia transient oliguria impaired urinary

Chart 4.

nitrogen excretion and renal changes at autopsy A 29 year old woman with a noncontributory past history received burns over 45 per cent of the body surface, chiefly deep and respiratory tract injury at the Coconut Grove fire. Initial surface treatment was triple dye following soap and water cleansing. Pulse on entry was weak and rapid. In the first 24 hours she received 11 units of plasma, 3 liters of saline and 1½ liters of glucose in water. She took 800 cubic centimeters of water by mouth. Her circulation improved over a period of hours and there were no further episodes of peripheral collapse. The urine output was 200 cubic centimeters in the first day and thereafter over a liter daily. Sulfadiazine was begun on the third day. The free drug level rose to 14 milligrams per 100 cubic centimeters of blood and the total drug level to 18 milligrams per

100 cubic centimeters of blood on the fifth day. Thereafter, the sulfadiazine was given intermittently with levels being obtained as given below under laboratory data. On the seventh day the temperature which had been 99 to 100 degrees rose remaining at about 104 degrees thereafter. She became markedly dyspneic and there were diffuse rales and crepitations rales throughout the entire chest. Pulmonary signs and symptoms increased and the patient expired on the twelfth day.

Laboratory data (see Chart 4) The patient had moderate hemoconcentration on the first day. She developed a marked anemia by the fourth day the hemoglobin remaining at about 55 per cent despite daily transfusions. The nonprotein nitrogen was 48 milligrams per 100 cubic centimeters of plasma on the first day 75 on the third day at about which level it remained thereafter. Sulfadiazine level on the fourth and fifth days was about 14 milligrams per 100 cubic centimeters of blood "free" and 18 milligrams per 100 cubic centimeters of blood "total." Thereafter the drug levels ranged from 3 to 3 milligrams "free" and 4 to 9 milligrams "total." The plasma total protein concentration was 5.9 grams per 100 cubic centimeters of plasma on the first day with a normal albumin/globulin ratio. Thereafter the total proteins ranged from 4.2 to 5.1 the normal albumin/globulin ratio continuing normal. The urine nitrogen excretion rose from 4 grams daily during the first 3 days to 12 grams daily from the ninth to twelfth day. Urine at the 16th hour dark brown hemoglobin 80 milligrams per 100 cubic centimeters pH 5.2 specific gravity 1010 albumin slight, trace hemoglobin casts hemosiderin, 2 plus. Thereafter the specific gravity ranged from 1013 to 1017 and the sediment showed an occasional red and white blood cell.

Autopsy findings The following were noted: burns covered 45 per cent of the body surface, chiefly deep acute laryngotracheobronchitis (inhalation) bronchopneumonia. The kidneys together weighed 310 grams. The cortex was pale and somewhat swollen. Microscopic showed the glomeruli were not remarkable save for vacuolated pink precipitates within the capsular space. The tubules contained casts of the two general varieties and presented evidence of tubular degeneration. The pigment casts were composed of granules varying from brown to red with an occasional smooth, blue homogeneous irregular mass. The other casts were composed of cellular debris which was eosinophilic and granular. Faint outlines of cells with nuclei were present in these casts. There were less casts of this type than there were pigment casts. Casts were not numerous. Usually a maximum of three casts per low power field (40X) could be seen. Casts were found in the collecting tubules and loops of Henle. Desquamated degenerated cells were present within the lumen of the tubules but regenerated epithelium was the predominant feature indicating previous tubule damage. Identification of the tubules involved in this process was often impossible.

Chart 5

It appeared that the convoluted tubules and possibly ascending limbs of Henle's loop were affected. The regenerated epithelium was not as high as was the older epithelium and took a distinctly more basophilic stain. Mitotic figures could be seen occasionally, indicating that the process was still active. The interstitial tissue was very edematous. Tubules were widely separated by pale loose stroma and between glomerular capsules and tubules there were widened clear areas. In a few areas newly formed fibroblastic tissue was present in the loose edematous stroma. In more or less discrete patches there was a moderate infiltration with plasma cells and a lesser number of lymphocytes. Only a rare polymorphonuclear leucocyte was found. No tubules were found containing polymorphonuclear leucocytes. It is not possible to say that the interstitial reaction bore any anatomical relationship to degenerated tubules or tubules with casts. Several large veins contained thrombi partially filling the lumen. These thrombi were composed of fibrin, enmeshed leucocytes, red blood cells and a red granular substance of undetermined nature. In the largest veins fibroblasts were invading the thrombi from points of attachment. The surrounding interstitial tissue contained plasma cells and newly formed fibroblasts.

CASE 2 Extensive deep burns shock hemoglobinuria azotemia oliguria edema and marked renal changes at autopsy. No diuretic effect from 50 per cent glucose or 25 per cent albumin intravenously. This 40 year old white female with a noncontributory past history received flame burns about 6 hours before entry as a result of an oil stove explosion. She felt fairly well at home and entered because of persistent pain. Examination revealed a fairly well developed and nourished woman with mixed dermal and deep burns of 30 per cent of her body surface. The blood pressure was 70/40 the pulse rapid and thready. Morphine $\frac{1}{4}$ grain was given subcutaneously and plasma started intravenously and within

the next 2 hours 1000 cubic centimeters of plasma and 800 cubic centimeters of 5 per cent glucose in saline were given intravenously. Her blood pressure rose rapidly to 120/80 and her pulse fell to 94 and was of good quality. The burns were then washed and silver nitrate and tannic acid were applied. In the next 8 hours her blood pressure gradually fell and the pulse rose to 140 and was of poor quality. The patient was given 1200 cubic centimeters of plasma in 2 hours with a rise in blood pressure and a fall in the pulse resulting and for the rest of the day her pulse remained about 100 and was of good quality. The blood pressure rose steadily reaching a level of 100/110 about 30 hours after entry but in the next 8 hours it had dropped to 130/90. There were no further episodes of hypotension or hypertension. The output was 200 cubic centimeters in the first 24 hours. Her hemoglobin fell from a level of 96 per cent on entry to 60 per cent in 48 hours. One thousand cubic centimeters of blood was given in the next 2 days but the hemoglobin remained about 60 per cent. Small petechiae were evident over the abdomen at 36 hours. The platelet count at this time was 18,000. The petechiae gradually increased until the entire abdomen and chest were covered. In the next 36 hours generalized edema became evident. This edema increased during the next day and then gradually disappeared with no evident diuresis or evidence of fluid accumulation in either the thorax or abdomen. The patient had been given aminophyllin at 30 hours and again at 40 hours with no apparent diuresis being obtained. The urine output remained low throughout the course and the plasma nonprotein nitrogen rose from 30 milligrams per 100 cubic centimeters plasma on entry to 130 on the fourth day (see Chart 5). Concentrated albumin and 50 per cent glucose were given on the second day and third day without producing any diuresis. From examination of Chart 4 it may be seen that 200 cubic centimeters of 25 per cent albumin intravenously produced a somewhat greater apparent increase in

Chart 6

blood volume as judged by the serial hemoglobin determinations, than 500 cubic centimeters of 50 per cent glucose. In the former instance the plasma protein concentration rose from 3.8 to 4.4, the rise being due to an increase in the albumin fraction, while in the latter case plasma protein fell from 4.8 to 3.8. The temperature had risen to 103 degrees on the second day at which level it remained. The pulse and respirations rose gradually beginning on the fourth day and the patient became irritable and stuporous and expired on the fifth day.

Autopsy findings: Burns involved 35 per cent of the body surface chiefly deep. Petchial hemo-
 rhages of the skin, testicular tract myocardium, renal pelvis and ureter were noted. Patient had rheumatic heart disease, inactive minimal bilateral hydrothorax 750 cubic centimeters pulmonary edema, peripheral edema (feet legs genitalia). The combined weight of the kidneys was 300 grams. On the cut surface and in the pelvis were found many minute yellow crystals which could be scraped away easily. There were several small cysts (1 mm. in diameter) in each kidney. The pelvis showed marked submucosal hemorrhage. Along the ureters there were many petchiae. Cortex and medulla were well demarcated. Microscopic examination

revealed that the glomerular capsular space contained a small amount of fine pink granular precipitate. The tufts showed no modification of the basement membrane, no cellular proliferation of infiltration, and the capillaries showed no congestion or thrombosis. The tubules contained moderate numbers of casts. These are most numerous in the medullary regions. A maximum of 20 per low power field were counted. The casts are composed of aggregates of red to blue fine granules mingled with which were small amorphous blue masses and a few desquamated cells (phloxine methylene blue). The majority of tubules containing casts could not be identified but an occasional collecting tubule, ascending and rarely descending limbs of loop of Henle were identified as containing casts. Rarely an intact tubule was found packed with cells. These cells often appeared to be macrophages containing yellow to red granules. In other instances there were cells with the appearance of desquamated epithelium. In 2 instances a few polymorphonuclears surrounded the casts. In Zenker fixed tissue stained for hemoglobin, the larger particles were olive green in contrast to the red stain taken by desquamated cell debris. Degenerative changes of tubular epithelium was not definitely found except at the sites of casts. However mitotic figures and regenerated epithelium and the finding of desquamated epithelial cells in casts was indicative of tubular damage. Many tubules of the medulla contained numerous large yellow particles. The interstitial tissue contains small foci of lymphocytes. Arterioles were not remarkable.

CASE 4. Extensive burns shock azolemia anemia and renal changes at autopsy. Diuretic effect 8 pm 25 per cent albumin intravenously. A 2 year old male infant with noncontributory past history entered the hospital 3 1/2 hours after receiving mixed dermal and deep hot water burns of 50 per cent of his body surface. Examination revealed a well developed and nourished apathetic infant. His color was ashen, extremities were cold and clammy. The blood pressure was unobtainable pulse was rapid and thready, rate about 160 and the peripheral veins were collapsed. Petrolatum pressure dressings were applied with no preliminary cleansing. On entry plasma was begun intravenously 50 cubic centimeters being given in 5 minutes following which the patient's color improved the pulse became stronger the rate dropped to 13 and he began moving about. The rate of plasma administration was slowed down and in the next 40 minutes 250 cubic centimeters of plasma were given. The patient became pale less active and the pulse was weaker. After the rate of administration of plasma was speeded up, the color and the quality of the pulse improved. During the next 5 hours he received 400 cubic centimeters of plasma and 200 cubic centimeters of water by mouth, the quality of his pulse and his color remaining good. About 10 hours after injury there was a brief period of peripheral collapse which responded to an increased rate of plasma flow.

Shortly thereafter the patient voided for the first time 30 cubic centimeters of clear light yellow urine. He was given 200 cubic centimeters of 5 per cent glucose in water intravenously in the next 2 hours. Fifteen hours after the injury the patient had a generalized convulsion. The respirations became rapid and gasping. Cyanosis was marked the pulse very rapid and weak. The temperature was 104 degrees rectally. The patient quieted down in a few minutes but the pulse continued to be rapid and of poor quality. The neurological examination was negative. Plasma was begun and after 150 cubic centimeters had run in his color improved and the pulse became slow and stronger. During the next 2 days the patient had a number of similar convulsive seizures despite fairly heavy sedation with sodium luminal. On the third day he had a much more prolonged seizure which lasted about 1½ hours. The pulse and respirations became very weak and rapid. Coramine and adrenalin were given intravenously with transitory improvement in pulse and respirations. Adrenalin was repeated twice more in the next half hour with the blood pressure rising to 110/80 at which level it remained thereafter. During the first 48 hours the patient received 250 cubic centimeters of plasma, 250 cubic centimeters of 5 per cent glucose in water intravenously, 200 cubic centimeters of 5 per cent glucose in water by clysis and 1500 cubic centimeters of water by mouth. There was some abdominal distention at 15 hours and gastric lavage yielded 150 cubic centimeters of coffee ground material. In the next 30 hours there was an additional 250 cubic centimeters of similar material vomited. The urine output was low during this time the total being 175 cubic centimeters in seven 25 cubic centimeter amounts in the period of 12 to 38 hours. In the next 30 hours the patient received 500 cubic centimeters of blood intravenously, 850 cubic centimeters of water by mouth, 100 cubic centimeters of 5 per cent glucose in water and 250 cubic centimeters of sodium chloride and sodium lactate solution. Aminophyllin and mercupurin were also given intravenously. There was 200 cubic centimeters of vomitus and two liquid guaiac negative stools. The patient had started to become more noticeably edematous 48 hours after entry and this increased definitely in the next 5 hours. There had been no urine output for the last 32 hours. At this time 35 cubic centimeters of 25 per cent salt-free albumin was given intravenously (Chart 5). In the next few hours there was a definite reduction of edema and some beginning bladder dullness which gradually increased. Nine hours later the patient was catheterized and 200 cubic centimeters of urine was obtained. At this time 35 cubic centimeters additional albumin was given. The following morning 200 cubic centimeters of 5 per cent glucose in water was given by clysis and 150 cubic centimeters of water was taken by mouth. The edema increased again and following the administration of 35 cubic centimeters more albumin there was some decrease in the edema. Two hundred and fifty cubic centi-

imeters of whole blood and 3¼ cubic centimeters of aminophyllin were given intravenously and 50 cubic centimeters more urine were obtained. During this period the patient was having loose tarry stools. On the fifth day he became comatose and the neck was somewhat stiff. Neurological examination was otherwise negative. Lumbar puncture revealed clear fluid pressure 300. The patient remained comatose and about 4½ days after entry the respirations gradually increased the pulse became more rapid and weak, and the blood pressure was unobtainable. The respirations became suddenly markedly labored and the respirations and pulse stopped in a period of a few minutes. His non-protein nitrogen which had been normal on the first day rose to a level of 100 milligrams per 100 cubic centimeters of plasma shortly before death (Chart 6).

Autopsy findings: The following were noted: Burns 35 per cent of the body surface mixed dermal and deep acute esophagitis (traumatic—laryngeal Levine tube) pulmonary edema pleural effusion and abdominal ascites (slight). The combined weight of the kidneys was 70 grams. The cut surface seemed swollen and appeared to bulge slightly. The pyramids were darker than usual. Microscopic examination revealed the glomerular capillaries congested the capsular space small and contained pink granular precipitate. There was no modification of the basement membrane or Bowman's capsule. The tubules contained numerous casts and showed extensive degeneration with marked regeneration of the epithelium. A maximum of 48 casts was counted in a single low power field (100X). The medullary region contained the greatest number of casts. The casts were of two main types: i.e. pigment casts and casts composed of desquamated tubule epithelial debris. The former were most commonly composed of moderately coarse granules of blue or dark green color. The individual granules often were of ovoid or round form. Less commonly the particles assumed larger rod like green forms. In some casts there were desquamated cellular elements. Pigment casts were found for the most part in collecting tubules or in the ascending portions of the loops of Henle. Most of the casts give a positive staining reaction for hemoglobin. The casts formed of desquamated necrotic cells were found in the cortex in convoluted tubules and in tubules that could not be identified because of extensive degeneration. These casts were composed of brilliantly eosinophilic finely granular material. No nuclear material could be seen. In some instances there were no remaining viable epithelial cells so that the cast was bounded only by the basement membrane of the tubules. In other instances flat basophilic regenerating epithelium was seen underlying the eosinophilic masses. Mitotic figures were numerous in the regenerating cells. Regenerated cells completely replaced degenerated cells in some instances. The tubules did not contain fat droplets of degeneration. There was no cellular infiltration or

fibrosis of the interstitial tissues and no scarring of Arterioles and renal pelvis were not remarkable

DISCUSSION

Observations on renal function and renal changes at autopsy in 47 patients have been described. The patients were separated for purposes of analysis into two groups on the basis of the morphological abnormalities of the kidneys. Group 1 included 20 patients (Nos. 1 to 20) in whom the kidneys at autopsy were abnormal. Group 2 included 27 patients whose kidneys were normal morphologically. Two patients (Cases 3 and 16) in group 1 were considered separately because the renal lesion found at autopsy was an acute pyelonephritis, entirely different from the renal lesion observed in all other patients of this group. In addition 3 patients in group 2 with extensive burns who died very early were considered separately. It is possible that in these cases there was not time enough for the appearance of morphological changes that might have been expected from the severity of burn in these patients. These 5 patients are excluded from the following discussion.

The anatomical abnormalities described here in the kidney of 18 patients of group 1 vary in degree of intensity from one patient to the other but are homogeneous in the whole group. Pigmented casts, epithelial casts, tubular necrosis and tubular regeneration, in cases surviving more than 2 days. The pigment casts were probably derived from blood pigments. This is indicated by the fact that they were indistinguishable from similar casts found in the kidneys of patients with hemolytic transfusion reactions, and is further confirmed by the presence of a positive staining reaction for hemoglobin in these casts. Furthermore there was a close correlation between the presence of hemoglobinuria during life and the presence of pigment casts at autopsy.

There was a close correlation between the clinical and laboratory findings of renal function and the pathologic observations on the kidneys. All patients in group 1 had evidence of persistent kidney dysfunction while only 1 patient in group 2 presented such evidence and in this patient it was secondary

to cardiac failure. In the few group 2 patients who had elevated levels of the blood non-protein nitrogen, the levels were on the whole much lower than in group 1 patients. In addition the two highest levels recorded in group 2 (Cases 33, 38) occurred late in contrast to the early high levels observed in group 1. There was also a contrast between the 2 groups of patients in respect to urine output. It is well known that during a period of shock of what ever cause there is a marked decrease in the output of urine (18). However in most patients in group 1 with oliguria, this output lasted the period of shock and persisted until death while in all but one group 2 patient the oliguria was limited to the period of shock and in this patient the oliguria was associated with cardiac failure. In those patients of group 1 in whom the oliguria was transient there was evidence of impaired ability to clear nonprotein nitrogen products in the face of a urine output of a liter or more daily.

A number of factors can readily be ruled out as responsible for the difference in renal changes in the two groups since these factors occurred with equal frequency in both groups. These are (1) age, (2) sex, (3) surface treatment, (4) fever (5) plasma protein concentration, (6) fluid intake. The intake of fluids was somewhat higher on the average in group 1 than in group 2. This is readily explained by the more extensive burns and higher frequency of shock in group 1. Since the shock in almost all the patients in group 1 was successfully treated it is probable that sufficient quantities of fluids were given so that their oliguria is not to be explained on the basis of insufficient fluid intake. The types and proportions of fluids given were the same in both groups. (7) Chemotherapy was not a determining factor since 12 patients in group 1 did not receive sulfadruugs. In no instance was hemolysis seen as a complication of drug therapy. (8) The organic mercurial preservative present in some of the plasma, serum and albumin was not responsible for the production of the renal syndrome since equal numbers of patients in both groups received mercury free fluids and mercury containing fluids. (9) Blood transfusion. The possibility that the renal lesion was produced by hemo-

lytic transfusion reactions can be ruled out since there were 8 patients in group 1 who did not receive blood at any time during their course, and in the remainder there was no evidence of a hemolytic reaction.

The 2 groups of patients differed mainly in respect to the following factors (10) extent of burn and especially extent of deep burn (11) occurrence severity and duration of shock and (12) presence of hemoglobinuria.

Extent of burn The chief complications of burns such as toxemia progressive anemia and nutritional disorders are directly related to the extent of burn and particularly the extent of deep burn. This holds true in regard to renal complications, since two-thirds of the patients with kidney dysfunction had deep burns of greater than 35 per cent body surface while only one-sixth of the patients without kidney dysfunction had burns of this severity. One patient (Case 1) in group 1 had a very small surface burn but had very extensive respiratory tract damage. There were 3 other patients in group 1 and 4 in group 2 who also had severe respiratory tract damage. The problem of respiratory tract injury as a complication of thermal burns has been discussed elsewhere by Finland, Davidson and Levenson.

Shock As would be expected from the fact that the patients in group 1 were the most severely burned the occurrence of shock in this group of patients was more common and more severe and prolonged than in the patients in group 2. This difference is important since shock *per se* is known to have a profound effect on kidney function. The occurrence of oliguria during shock is well recognized and is presumably due to a markedly decreased blood flow through the kidney (18). The blood flow through the kidney may be reduced to as low as 5 per cent of its normal value during shock at a time when the general blood flow is only reduced to 50 per cent (18). That the renal failure observed in shock associated with burns may be different from that seen in other types of shock is suggested by the experiments of Olson and associates on dogs. They showed that in burn shock restoration of the blood pressure by infusions of saline did not increase the output of urine

while such infusions did increase the urinary output in hemorrhagic and tourniquet shock. The effect of shock on renal function is related to the severity and duration of the shock. Disturbances in renal function are more severe and more protracted when the shock is profound and lasting. Irreversibility of the function and morphologic alterations of the kidneys following severe shock have been described by Van Slyke. He showed that severe reduction in the renal blood flow during circulatory failure for a period of hours following hemorrhage is often followed by markedly impaired kidney function and pathologic changes in the kidneys consisting chiefly in tubular necrosis and the presence of pigment casts in the tubules.

Hemolysis The third factor of apparent importance in the pathogenesis of the renal injury following burns is intravascular hemolysis, since renal injury has been observed in a number of other conditions in which intravascular hemolysis occurs (2,7,21,28,32). Intravascular hemolysis occurs in all severely burned patients and is apparently caused by a direct action of heat on the red cells of the blood circulating in the burned areas (23). Its occurrence and severity are directly related to the extent of deep burn and, as would be expected, hemoglobinemia was greater in the patients in group 1 than in group 2. Hemoglobinuria was seen in nearly all the group 1 patients and in only 1 patient in group 2.

Monke and Yule in dogs and Altschule in men have demonstrated that hemoglobin is excreted in the urine only when the levels of free hemoglobin in the plasma reach values of about 150 milligrams per 100 cubic centimeters of plasma. Below this concentration it is apparently completely reabsorbed from the glomerular filtrate by the renal tubules. In chronic hemoglobinemia in dogs the threshold is lower which has been explained by a supposed saturation of the tubules with pigment derived from red cells (32). When hemoglobinemia is associated with shock the conditions for the appearance of hemoglobinuria may be different. Absence of hemoglobinuria in the presence of a marked hemoglobinemia in such cases could be due to

the decreased glomerular filtration caused by the vascular hypotension and the decreased renal blood flow. Furthermore if anuria of whatever cause is present as was the case in one of our patients, and as has been reported by DeGowin it is obvious that no hemoglobinuria can occur even in the presence of marked hemoglobinemia.

If the renal damage is a direct toxic effect of the products of intravascular hemolysis it can be produced only if the products of red cell hemolysis reach the kidney tubules. This seems likely since in these cases hemoglobinuria and not merely hemoglobinemia is associated with renal lesions. On the other hand, it may be just a question of degree of hemoglobinemia, since hemoglobinemia was more marked in the patients with hemoglobinuria than in those without hemoglobinuria.

Renal injury sometimes of a severe nature is sometimes seen following hemolytic blood transfusion reactions. The renal syndrome of hemolytic transfusion reactions includes oliguria or anuria, azotemia and often uremia. Morphologically the kidney changes such as pigmented casts in the tubules and tubular necrosis are strikingly similar to those seen in patients with severe burns. Here also as in the kidneys of burn patients, there is no apparent correlation between the number of casts and the extent of tubular necrosis (7). Other types of intravascular hemolysis have also been shown to affect the kidneys in a similar fashion. Renal failure has been described in cases of paroxysmal nocturnal hemoglobinuria (21), hemoglobinuria due to quinine poisoning (28), black water fever (31), acute hemolytic anemia due to sulfonamides (12) and hemoglobinuria of obscure origin (2).

The mechanical obstruction which may be caused by the pigment casts in the tubules seems quantitatively inadequate to explain the renal failure. It is possible that the tubular necrosis may play a part although the extent of tubular necrosis again does not seem sufficient to account for the failure. The sections of the kidney provide no information on the function of the glomeruli which may be impaired although their structure appears

normal. The identity of the substance or substances in hemolyzed blood which are responsible for the kidney injury and the mechanism of action are still debated. In dogs reduced hemoglobin and oxyhemoglobin do not appear to be toxic, while methemoglobin appears to be toxic in the presence of an acid urine. If the urine is alkaline methemoglobin is also nontoxic (4). It has been shown that when intravascular hemolysis occurs, part of the hemoglobin is oxidized to methemoglobin (27). The application of these observations to the cases studied here is obvious when one remembers that methemoglobin has been found in the blood and urine of burned patients (23, 24) and that the initial urines of most burned patients are acid. It is also possible that the products of hemolysis are particularly toxic to the kidneys of patients in shock. Under the conditions of relative ischemia and anoxia, the kidney may be more susceptible to injury. Yule and his associates have shown recently in experimental animals that renal injury by hemoglobin occurred only when the kidney had been damaged previously. Another possibility is that some other constituent of the red blood cells set free during hemolysis, for instance the stroma, is toxic since solutions of hemoglobin are much less toxic than is hemolyzed blood (33).

The problem of the toxicity of hemolyzed blood is intimately linked with the question whether alkalization of the urine is in any way preventative of renal damage. This question in relation to the kidney dysfunction in patients with burns cannot be solved on clinical grounds alone since practically all severely burned patients have an acid urine when they are admitted to the hospital and intravascular hemolysis has already existed for at least an hour before alkalization of the urine is attempted. No studies in animals comparable to those of Baker and Dodds on the effect of alkalization on the renal damage following hemolytic blood transfusion reaction have been made. The effect of alkalization of the urine after hemolysis has been present cannot be evaluated from the data reported here since despite the administration of alkali on entry the urines remained

acid during the first 12 hours in most patients Walker reported no benefit from early alkalization in his patients with burns

The renal syndrome of severe burns is similar to the renal syndrome associated with crush injuries. The urine in the latter syndrome, however, contains myoglobin rather than hemoglobin and the pigmented tubular casts have also been shown to contain myoglobin (5). It is believed that the myoglobin originates from the crushed muscles. Idiopathic paralytic myoglobinuria which is rarely encountered in man but is occasionally seen in horses is also characterized by myoglobinemia and myoglobinuria and a clinical and pathologic renal picture entirely similar to that found after crush injury. Shen and Ham and Taylor and associates (24) have looked for myoglobin in the blood and urine of some burned patients but in no case was any found. Kidney dysfunction and renal changes similar to those described here have also been reported following severe traumatic injuries (noncrush) with shock.

The azotemia observed in this series of patients deserves special comment since it may be due in part, to an increased production of nonprotein nitrogen in the presence of a failing kidney. The very rapid rise in nonprotein nitrogen values observed is best explained by a factor of increased production together with decreased excretion. This view is further supported by the fact that there is an increased breakdown of proteins in burns (25).

Partition studies of the nonprotein nitrogen products in the blood and urine of some of these patients with azotemia have revealed an increase in the residual nitrogen fraction (25,30). This has not been found in all patients with clinical and pathologic changes. Its significance is not known at present.

There is no evidence in the present series of cases that aminophyllin or hypertonic glucose solution intravenously led to any diuresis in the patients with impaired renal function. In 1 case following the administration of albumin intravenously there was an increase in urine output. In 2 other patients to whom albumin was given for a possible diuretic effect, there was no increase in urine output.

It would appear that a very important measure to be taken for preventing renal damage is the prompt and vigorous prophylaxis and treatment of shock. The efficacy of early alkalization has not been definitely evaluated. The injection of reducing agents to reduce the methemoglobin appears logical but has had no adequate clinical or experimental trial. Once renal dysfunction has appeared care must be taken in the administration of fluids particularly sodium-containing fluids, to avoid overloading the circulation. Aminophyllin and hypertonic glucose have not proved useful diuretic agents and the latter in the presence of hypoproteinemia may lead to dangerously low plasma protein concentration. Albumin should be tried, particularly if there is hypoalbuminemia and peripheral edema. A possible danger would be the production of pulmonary edema. The use of diathermy (19) x ray (29), decapsulation (1), sympathectomy (20) and spinal anesthesia (20) have not been evaluated.

It should be mentioned that most of the patients with renal dysfunction died of causes other than renal failure. However it is possible that if these complications can be avoided the patient would go on to death from renal failure. In such cases it would be useful if measures could be taken to tide the patient over until renal tissue has had an opportunity to regenerate and, possibly function to be restored. Extravascular (26) or peritoneal dialysis (22) might be useful if they can be carried out practically and successfully.

SUMMARY

1 Forty-seven patients with burns were studied in an attempt to establish a correlation between kidney function during life and morphologic kidney abnormalities at autopsy.

2 Twenty patients had abnormal kidneys at autopsy and except in 2 cases which showed pyelonephritis the renal lesions consisted of tubular necrosis and the presence of pigment and cellular casts in the tubules. The remaining 27 patients had no significant renal morphologic changes.

3 The pigment casts gave positive "hemoglobin stains" but no more specific identification was made.

SURGERY GYNECOLOGY AND OBSTETRICS

4. Clinically kidney dysfunction was manifested by persistent azotemia oliguria, decreased urinary nitrogen excretion, and rarely edema. Renal dysfunction was probably the cause of death in 2 patients.

5. A close correlation was found among renal dysfunction morphologic abnormalities of the kidneys and extent of deep burn severity of shock, and presence of hemoglobinuria.

A NEW METHOD OF TREATMENT FOR SEVERE FRACTURES OF THE OS CALCIS

A Preliminary Report

KENNETH H PRIDIE, F.R.C.S., Bristol England

IN the past a fracture of the os calcis was a relatively rare injury confined very largely to window cleaners. Modern warfare however with the introduction of the torpedo land mine paratroop landings, and other features of warfare has increased not only its absolute incidence but also the relative frequency of the severe highly comminuted type. Despite the most energetic treatment the resultant disability remains a serious one. Patients are left with persistent pain stiffness inability to walk over rough ground or do ladder work or indeed any form of hard manual labor.

In those cases in which the subastragaloid joint has not been affected early movements

from the Fracture and Orthopaedic Departments of the Bristol Royal Hospital

and freedom from weightbearing for 6 weeks produce good results, and the patients are able to return to their preaccident occupations. But in others even when the fracture does not appear to be a serious one subastragaloid arthritis develops out of all proportion to the x ray findings so that the end result is much worse than would be expected the disability consisting as before, of pain and stiffness. Despite individual variations in tolerance to pain the findings in a large number of patients are remarkably consistent.

Several views of a fractured os calcis were taken and from these the upper surface of the os calcis has been reconstructed as shown in Figure 1. The disruption and distortion of the subastragaloid joint can be seen. Any form of treatment to correct and get fair alignment of this complex joint surface is obviously impossible. Consequently the patient develops a severe subastragaloid arthritis.

The lateral view which is illustrated in Figure 2 shows how the os calcis has been broken on the wedgeshaped lower border of the astragalus.

Fig. 1. Reconstruction of the upper surface of a badly fractured os calcis.

Fig. 2. Lateral view showing os calcis broken on wedgeshaped lower border of astragalus.

Fig. 5. Condition of foot at operation grossly edematous over heel.

patient lying prone an incision 5 inches long was made in the midline from 1 inch above the back of the os calcis over the point of the heel to the anterior end of the bone. In dissecting the two flaps care was taken not to separate the skin from the deep structures in order to preserve its blood supply. The plantar fascia was split longitudinally. The os calcis was sawed in two along its long axis and shelled out so as to leave intact the periosteum and the fibers of the Achilles tendon which pass over the bone to become continuous with the plantar fascia.

Fig. 6. Incision. Foot in sterile stockinette.

Fig. 7, left. Exposure of os calcis. A Cut edge of plantar fascia.

Fig. 8. Os calcis completely removed. Astragalus exposed. A astragalus B tendon peroneus longus C flexor hallucis longus D, flexor digitorum longus, E, soggy edematous tissue in joint, seen after removal of os calcis.

Fig. 9. Suture of wound. Incision closed. Restoration of normal outline.

The cortex of the os calcis was extremely thin and the fragments spike like, resembling a broken glass bottle. Figure 4 shows the fragments removed at an operation for excision of the os calcis.

The under surface of the astragalus could be easily seen and was not fractured. It was noted that there was great swelling and bruising of the soft tissues and it is undoubtedly the tension in them which leads to the fibrosis which causes so much stiffening of the joints and the small muscles. The operation not only removes the damaged bone and joint surface, but also relieves the soft tissue tension and reduces the general rigidity of the foot. The wound was closed by suturing the insertion of the Achilles tendon, now freed from bone, to the plantar fascia. The two halves of the periosteum and the skin and fascia were sutured in layers with cotton. Two gauze pads were placed on each side of the heel to maintain its natural shape and the usual dressings and a firm bandage were applied. The foot was then immobilized in plantar flexion with plaster of Paris.

When the plaster was removed 10 days later the wound was soundly healed and active movements were commenced. Two months after the operation the patient started walking, and was discharged after 3 months. A year later she walked well and was able to dance. At 18 months she walked without a limp, had no complaints, and stated that she was able to do anything. She could stand on tip-toe and when walking it was impossible to tell which foot had been injured. There was no loss of power and she had full range of inversion and eversion, and freely mobile metatarsal and toe joints. In appearance the foot was perfectly normal.

CASE 2. A man DGF, aged 62 years, fell a distance of 10 feet on to a concrete floor on December 21, 1942 and sustained a comminuted fracture of the left os calcis. He was operated on the next day and almost the whole os calcis was removed except the anterior inch. He was able to go back to work after 6 months and has been at work ever since. He walks normally and is able to run. He can stand on tip-toe and there is no visible lack of power in the left leg. The Achilles tendon appears to be as strong on the left side as the right. The appearance of the foot is good and all movement are excellent.

AFTER TREATMENT

The foot is immobilized in the original plaster for 1 month. The position of plantar flexion is to ensure relaxation of the Achilles tendon so that its new attachment is not strained. At the end of 4 weeks the sutures are removed and active nonweight bearing exercises are commenced. The important exercises are inversion, eversion and circumduction. Posttraumatic edema is prevented by insisting that the leg be not allowed to hang down during the 2 weeks immediately follow-

ing removal of the cast except during periods of exercise.

When the patient feels able to walk he is encouraged to do so. The average period is about 6 weeks. It is important to see that he is taught to walk correctly and without a limp.

RESULTS

This new method of treatment of fractures of the os calcis has been performed 15 times to date and the 2 cases reported were the first and therefore have been observed over a considerable time. Three years have now elapsed since the first operation was performed and this girl has an excellent result with practically no disability. The second patient, a bricklayer, has now been working for 2 years, without disability.

Two cases were not satisfactory. One a man aged 63 fell 14 feet from a plank directly on to his left heel with the knee straight. He sustained a very severely comminuted fracture of the left os calcis and the os calcis was removed. He made a very poor recovery and got causalgic pains in his leg and at a later date the leg had to be amputated. The section of the foot afterward showed that there was a condition of arteriosclerosis present and he had very poor circulation. There was arthritis in all joints of the foot which was completely stiff and rigid. Whatever treatment this man had he would have had a poor result. Another patient for whom the os calcis of both feet was removed was an old man who had fallen 20 feet and landed on his heels. He also had a very poor result. These were the only two really bad results out of the 15 cases I have done and all the rest of the patients are doing exceptionally well.

CONCLUSIONS

The results of this operation have been so gratifying that this preliminary report is published in order that others may try it. It probably should be reserved for the severely comminuted fractures and like other excisions of bones in the foot it is a somewhat difficult operation because of the strong ligaments attached to the bone. Unless one is careful to avoid a postoperative hematoma there is risk of sepsis. The operation should

be performed as soon as possible after the injury in order to prevent intrafascial tension from bleeding and edema which causes ischemia and subsequent congealing of the intrinsic muscles and leads to stiff midtarsal joints and stiff toes. Careful attention must be paid to the after treatment.

The chief advantages of this method are

- 1 Freedom from pain
- 2 Good range of inversion and eversion
- 3 Mobility of the whole foot
- 4 Good toe action
- 5 This operation will undoubtedly save many an injured foot from amputation

LARGE RETROPERITONEAL METASTASIS FROM A SO CALLED CARCINOID OF THE SMALL INTESTINE

JAMES A. DICKSON M.D. EDITH M. PARKHILL, M.D. and
PAUL C. KIERNAN M.D., Rochester, Minnesota

CARCINOMAS of the small intestine are comparatively rare comprising about 3 per cent of all intestinal cancers. The so called carcinoid tumors constitute approximately a fourth of all malignant neoplasms of the small bowel. These tumors have also been termed argentaffinomas, chromaffinomas, paragangliomas and primary carcinomas. They occur at least two times more frequently in the appendix than in the small bowel. However this type of neoplasm has been known to occur in all locations of the gastrointestinal tract from cardia to anus. In the small intestine carcinoid tumors are characterized particularly by occurring in older persons and by the multiplicity of their primary lesions in contrast to the single primary lesions occurring in the appendix, which are seen most frequently in younger persons. The present report is concerned with a single small primary growth in the ileum with extension into the mesentery and a large retroperitoneal metastasis of both surgical and pathologic interest.

HISTORICAL ASPECTS

Credit is due to Lubarsch who in 1888 clearly distinguished these neoplasms from ordinary adenocarcinomas occurring in the gastrointestinal tract. He reported 2 cases of multiple nodules in the ileum and designated

From the Division of Surgery, Mayo Foundation, and from the Section on Surgical Pathology and the Division of Surgery, Mayo Clinic.

the lesions as primary carcinomas although they appeared somewhat atypical. Ransom in 1890 described 1 case resembling that of Lubarsch in which the neoplasm had spread into the mesentery and metastasized to the liver.

It was Oberndorfer who in 1907 termed these neoplasms carcinoids to express their malignant appearance in contrast to their benign clinical course. Based on a study of 6 cases of multiple tumors of the small bowel Oberndorfer's description of these neoplasms in summary is worth quoting in part in Forbus translation because some of the points may merit criticism in light of the behavior and character of lesions as reported since that time.

- 1 The tumors are usually multiple
- 2 The cells are largely undifferentiated masses but may show glandular form
- 3 They are circumscribed and have no tendency to infiltrate the surrounding tissue.
- 4 Growth is slow no large size being obtained.
- 5 The tumors are of a harmless character
- 6 They lie regularly in the submucosa with frequent projections into the mucosa.
- 7 The stroma is smooth muscle derived from muscularis.

We shall not comment in detail on the foregoing points of Oberndorfer's description suffice it to say that carcinoids certainly are not to be regarded as benign and harmless, especially when located in the small bowel.

In contrast to the conception of Oberndorfer and in support of Bunting, Burckhardt con-

Fig. Relation of small bowel to the retroperitoneal mass.

considered these neoplasms definitely of basal cell character and analogous to the basal cell cancers of Krompecher. While microscopically resembling basal cell epitheliomas superficially, these tumors, unlike basal cell cancers, will definitely metastasize as is indicated in reports published within recent years.

ORIGIN OF THE SO CALLED CARCINOID TUMORS

The exact cell or cells of origin of these tumors have not been conclusively demonstrated and authorities are not agreed. The weight of the evidence seems to be in favor of their origin from the argentaffin cells found distributed irregularly in the gastrointestinal tract and notably within the crypts of Lieberkuhn. The three types of granular cells located in the intestinal tract and described by Schmidt, Kulschitzky and Paneth all seem to be implicated as possible sources of these neoplasms. It was Gosset and Masson (7, 11) who first showed that certain cells situated at the bases of the crypts of Lieberkuhn reduce an ammoniacal solution of silver salts. The granules in these cells are stained by the chromaffin and silver impregnation methods and by various other stains, perhaps depending on their different functional stages. No explanation of the histogenesis of carcinoid tumors of the small intestine can be accepted without some degree of reservation (3). There may be a common cell of origin or any of the

three types mentioned earlier in this paragraph and described in detail by Kull may be their source under various situations.

PATHOLOGIC ASPECTS OF SO CALLED CARCINOID TUMORS OF THE SMALL BOWEL

As mentioned previously these lesions occurring in the small intestine are frequently multiple and occur in an older age group than those found in the appendix, which are usually single (17). The primary tumors are characteristically small in contrast to the much larger metastatic foci. They are characteristically yellow and frequently one may suspect the diagnosis grossly after sectioning the lesions. Most frequently the lesions do extend into the mucosa and lumen of the bowel but this is not always so. In some cases the lesions seem to extend outward into the muscular coats with little or no projection into the lumen. Their growth in the intestinal wall results in kinking or angulation of the involved segments. Gross ulceration of mucosa may be absent a fact that explains the absence of intestinal bleeding in many of these cases.

Microscopically these tumors consist of cuboidal, spherical, or cylindrical cells arranged in small irregularly shaped groups or masses. The nuclei are vesicular and rounded or ovoid. The cell groups or nests are usually predominantly solid. The lesions are usually seen in the muscularis mucosae and extend into the mucosa and muscular coats of the intestinal wall. The cytoplasm of these cells has usually an indistinct border and is finely granular. These granules are both chromaffin and argentaffin. The cells on the outermost border of the masses or groups frequently may be seen to be arranged in parallel fashion and assume a cubical shape recalling a similar pattern seen in basal cell cancers. This feature is more prominent in the fresh frozen sections than in the fixed paraffin sections showing the tumor cells. The cytoplasm of the tumor cells may be finely vacuolated because of the presence of the lipid material to which the yellow color of the tumor is due. The relative uniformity of pattern of these groups or masses of cells, the lack of hyperchromatism, the regularity of their nuclei and partial opacity seem to indicate low malignancy. Close examina-

a

b

Fig. 2 a. Primary lesion showing tumor cells in and beneath the mucosa of the ileum (hematoxylin and eosin, $\times 27$)

b. Argentaffin tumor cells arising in mucosa of small bowel (Masson silver impregnation method, $\times 27$)

tion of the histopathologic features of these neoplasms of the small bowel does not seem of value in distinguishing those which have metastasized from those which have not metastasized and the picture seems to be similar in the two instances.

These neoplasms are carcinomas and are characterized by slow growth. Burckhardt remarked that "Metastasis from carcinoids is merely a matter of time." The malignancy of those in the small intestine is manifested much more frequently than the malignancy of those occurring in the appendix. Docherty, Ashburn, and Waugh (4, 5) noted metastasis in at least a third of their cases in which the neoplasm occurred in the ileum.

The carcinoid type of carcinoma spreads by the lymphatics and by venous invasion by the tumor cells. The likeness of these neoplasms to basal cell epitheliomas here terminates because the latter do not metastasize per meate lymphatics, or invade veins.

The term "carcinoid" may be a good term only so far as it distinguishes these neoplasms from other ordinary adenocarcinomas of the

intestinal tract. However, it should be emphasized again that these tumors are not harmless or benign but malignant and that they will infiltrate and metastasize and may eventually result in the death of the patient. Some reports of cases in recent years have even indicated disseminated metastasis as in the case reported by Watz. Even with metastasis in the liver and other widespread regions it should also be emphasized that provided the primary tumors are removed, the patient may live for many years in good health, as may be anticipated from the very slow growth of some of these tumors. In spite of their slow growth and mild clinical manifestations in many cases, we consider these neoplasms carcinomas.

CLINICAL ASPECTS

Symptoms, when present, are usually those of a chronic intestinal obstruction resulting from kinking of the involved segments of the bowel. Intussusception of the bowel may occur. Bleeding into the intestinal tract is most frequently absent. The patient is usually not very ill and most often loss of weight

Fig. 3 a, Perusey al collection of tumor cells from mesenteric metastatic focus (hematoxylin and eosin, X180)

b, Not deeply stained endothelial cells lining perivascular space (Schmorl's method for chromaffin cells, X80).

is not pronounced. In some of these cases the neoplasms are reported as being silent but in the small bowel they frequently give symptoms of obstruction. Occasionally there may be a palpable abdominal tumor.

Roentgenographically, one may be able to demonstrate slight kinking and angulations of the involved portions of intestine associated with a small tumor projecting into the intestinal lumen. The kinking and the tumor may be the only signs demonstrable.

SURGICAL ASPECTS

The ideal surgical management for carcinomas of the carcinoid type involving the small bowel is resection of the segments of bowel containing the small single or multiple primary lesions with removal of all metastatic foci when feasible, including the involved lymph nodes. It is only in very rare instances because of the size and strategic location of metastatic masses, that it may be inadvisable to attempt their complete removal. However, when removal of the primary lesions has been performed, even with metastatic involvement, the prognosis may be good because of the slow growth of these neoplasms. When patients with metastatic foci located retroperitoneally in the liver or in other locations have had the segments of small bowel containing the primary tumors resected, followed by anastomosis of the remaining segments of bowel they have been known to live for many years.

It is important not to overlook multiple small primary lesions throughout the extent of the small bowel or even in the large bowel in these cases at the time of operation. The primary lesions may be very small and difficult to palpate but their presence may be manifested grossly by a slight kinking or angulation of the involved segment or segments of the bowel.

It is not possible to state whether removal of the primary tumor may have a beneficial effect on the metastatic foci from neoplasms of this type. Because of their slow growth metastatic tumors may be present for a long time without revealing their presence.

In summary the ideal form of surgical management seems to be as radical a removal of the primary lesions and any metastatic foci

as is feasible. When resectability is limited to removal of the primary tumor or tumors, the prognosis may be good and the patient may live for many years in health sufficiently satisfactory to carry on all normal activities in spite of even large metastatic foci.

REPORT OF CASE

The patient a former nurse was a woman 65 years of age who appeared in fair general health. She was first seen at the Mayo Clinic July 16, 1945 when she stated that she had been fairly well until 5 years ago at which time she became constipated and began to take daily laxatives. At no time had she noticed any bleeding from the gastrointestinal tract. A series of roentgenographic studies had been done and at this early period her condition was diagnosed as spastic colon. Two years ago she noticed no improvement and had a second series of roentgenograms taken. At this time she was told that there was nothing abnormal to be found in her intestinal tract. She had complained for the past year of pain in the right upper quadrant of her abdomen which had been relieved for short periods by colonic irrigations. She had not noted any bleeding or tarry stools. There had been no nausea or vomiting. There had been no jaundice or colic of any kind within recent years. Systemic review revealed a history of low back pain during the past year which she had noted most severely during change in position. Appendectomy had been performed 15 years ago and Ovarian cystectomy had been performed 4 years previously.

Physical examination. The systolic blood pressure was 140 millimeters of mercury and the diastolic pressure 88. The pulse 80 and the temperature 98.6 degrees F. The important physical findings were largely limited to the abdominal examination. There was a rather large cylindrical, firm slightly tender mass located in the midabdomen, extending longitudinally to the right of the midline and measuring approximately 10 centimeters in length and 6 centimeters in width. The mass was medial to the usual position of the cecum and was only slightly movable. No other masses were palpable.

Clinical studies were then made. The excretory urogram was essentially negative on each side. Studies of the colon also gave negative results and a simple roentgenogram showed only an opaque real due in the colon. The abdominal field was otherwise negative roentgenographically. Complete studies of the blood and urinalysis revealed normal findings.

Operative procedure (abstracted in part). Operation, consisting of resection of a portion of the ileum, ileostomy (side-to-side) and removal of a specimen from the retroperitoneal tumor for diagnosis was performed by one of us (P. C. K.) on August 7, 1945. The operative diagnosis was retroperitoneal malignancy. The tumor with involvement of the mesentery of the small bowel and primary lesion in the small bowel.

Examination of the stomach, colon and first portion of the duodenum gave negative results. The gall bladder was distended and thin walled but contained no stones. The liver and pancreas were normal. On examination of the pelvis, it was observed that the uterus was atrophic and the adnexa were negative to palpation. The small bowel was normal throughout the jejunum and upper part of the ileum but about the midileum the mesentery was much shortened and was attached to a retroperitoneal mass. There was a slight kinking or angulation in this portion of the ileum and a small nodule could be seen extending to the serosal surface. At this same segment of the ileum approximately 3 feet (91 cm.) of the lower portion of the ileum was closely adherent to this mass. The tumor although not completely fixed, involved the entire root of the mesentery of the small bowel and was closely adherent to the large vessels. Figure 1 illustrates diagrammatically the relative position of the retroperitoneal mass and its relationship to the small bowel. It was thought best not to attempt removal of the retroperitoneal mass. Approximately 3 feet (91 cm.) of the lower part of the ileum was resected including the involved indurated portion of the mesentery, the ends of the bowel were turned in and a side-to-side anastomosis was performed. The anastomosis was about 3 to 4 feet (91 to 122 cm.) proximal to the ileocecal valve and seemed satisfactory. The appendix had been removed previously elsewhere. Biopsy of two specimens from the retroperitoneal mass was performed for diagnosis.

Pathologic aspects The resected portion of the ileum contained a small rounded nodule measuring 1.4 by 1 centimeter located within the wall of the ileum and extending to the serosal surface and also several irregular nodules located within the mesentery of the ileum just beneath the primary lesion. The cut surface of the primary lesion was smooth and yellow and the lesion appeared to involve predominantly the submucosa and muscularis but did not project into the lumen of the small bowel. The involved mesentery was firm and irregularly shaped and appeared more whitish than the yellow primary lesion. The two small pieces of tissue from the retroperitoneal mass presented an occasional yellowish spot within their substance. Microscopically sections from the primary lesion from the involved mesentery and from the retroperitoneal mass were all similar and characteristic of those of carcinomas of the carcinoid type. The tumor cells were all microscopically identical in each location. The tumor cells were arranged in solid groups or masses made up predominantly of spherical cells. The cytoplasm was finely granular with indistinct cytoplasmic borders and the nuclei were small rounded or ovoid and vesicular. The fine granules within the cytoplasm of all these tumor cells in each location were both argentaffin and chromaffin. Figure 2 shows one of the sections taken from the small primary lesion within the wall of the ileum. Figure 3 illustrates one of the sections taken from the involved mesentery of

the ileum. Figure 4 is representative of one of the sections taken from the retroperitoneal mass. It is evident that the small lesion in the wall of the ileum was the primary site and that the nodules in the mesentery and the large retroperitoneal mass, which greatly exceeded the volume of the small primary lesion, were metastatic foci. All of these locations, including the primary lesion in the ileum showed carcinoma of the carcinoid type.

Postoperative course The postoperative course was uneventful and the patient was dismissed from the hospital August 14, 1945 and from the clinic August 24, 1945 in a satisfactory condition.

COMMENT

Some of the important surgical and pathologic aspects of carcinomas of the carcinoid type involving the small bowel have been previously discussed.

The case herein reported of a so called carcinoid presented several unusual features of both surgical and pathologic interest. It was illustrative in many respects of these tumors occurring in this portion of the small bowel except that in this case there was only a single primary lesion. However the rather extensive involvement of the mesentery and the large retroperitoneal metastasis were unusual features. The most unusual feature of this case was the strategic location of the large retroperitoneal mass at the root of the small intestine in proximity to the great vessels in such a manner so as to make its removal inadvisable to attempt. In spite of the fact that it was not possible to remove the large retroperitoneal mass, it was possible to remove the primary lesion and the involved mesentery and thus avert any future threat of obstruction which indeed is one of the most likely complications with neoplasms of this type involving the small bowel.

SUMMARY

A case of so called carcinoid of the ileum with a large retroperitoneal metastasis has been presented. The strategic location of the large retroperitoneal mass at the root of the mesentery of the small bowel prevented any attempt at excision but it was possible to remove the primary lesion in the ileum with the involved mesentery and thus relieve any further possibility of obstruction. The case presented illustrates well the fact that these neoplasms can no longer be regarded as benign.

DICKSON ET AL. RETROPERITONEAL METASTASIS

and harmless. We consider these so called carcinoids of the small bowel to be grade 1 (Broders method) carcinomas of the carcinoid type in order to distinguish them from the ordinary adenocarcinomas of the intestinal tract. Designation of these neoplasms as grade 1 carcinomas indicates their slow growth and low malignancy. It is felt that the histopathologic picture of those neoplasms which have metastasized is similar to the picture of those which have not metastasized. Therefore one is unable to predict on the histopathologic basis which of these neoplasms will metastasize.

INTRATHORACIC TUMORS OF THE SYMPATHETIC NERVOUS SYSTEM

R. K. HOLLINGSWORTH, M.D. F.A.C.S., Washington, D.C.

NEOPLASMS of the sympathetic nervous system are widely distributed, having been reported as occurring in the adrenal (most frequent site) abdominal cervical, thoracic, and pelvic sympathetics the jejunum, celiac ganglion, mesentery, liver coccygeal body uterus, cavity of the nose skin and subcutaneous tissue, scapula region and carotid body. Their occurrence within the thorax while not rare, is still unusual enough to warrant their being classified as a curiosity by Gray and to justify the continued reporting of individual cases or small groups of cases. More often than not, they are symptomless their discovery being quite accidental. For this reason an accurate estimate of their incidence can not be made. Mass chest x ray surveys such as preinduction pre-employment, and school examinations will inevitably lead to the more frequent discovery of intrathoracic neoplasms, and their removal and consequent correct diagnosis will follow.

The present communication deals with the occurrence of these neoplasms, the embryology of the sympathetic nervous system in its relation to their formation, a discussion of their characteristics and a detailed report of 7 cases which have occurred at the University of Michigan Hospital. In addition the author has found 63 cases of intrathoracic sympathetic tumors reported in the literature. Of these 43 or 68.2 per cent were ganglioneuromas, 16 or 25.4 per cent sympathoblastomas (neuroblastoma) 2 or 3 per cent sympathogoniomas and 2 or 3 per cent pheochromocytomas.

OCCURRENCE

Gray states that in 1864 Knoebellanch reported the first ganglioneuroma in the case of a neuroma reported by Odier in 1803. The

tumor was undoubtedly a ganglion cell tumor. The first tumor from the sympathetic nervous system to be adequately described was reported by Virchow in 1864, designated by him as a glioma but believed by Wahl and others to have been a ganglioneuroma. Lorets in 1870 first described ganglioneuromas and reported the first intrathoracic case. But it was not until 1910 that Wright placed these tumors on a sound pathological basis. He called attention to a group of tumors, the nature of which had previously escaped general recognition, and he pointed out their distinguishing characteristics. He considered the essential cells of the tumors to be more or less differentiated nerve cells, neurocytes or neuroblasts, and designated these tumors as neurocytoma and neuroblastoma. Paragangliomas or the chromaffin tumors were first described by Mannasse in the suprarenal gland in 1893. Frankel in 1886 and Perley in 1890 described tumors apparently of this type.

True nerve tumors, i.e., growths consisting of specific nerve tissue elements, may occur in any part of the nervous structure. They may be benign or malignant and while they may differ widely in their structure, behavior and occurrence, yet they are closely related ontogenetically. Both the benign and malignant forms are well illustrated in the sympathetic system. The benign form includes the ganglioneuromas and the chromaffin tumors, in both of which the cells are more or less highly differentiated. The malignant form, not recognized as such until Wright's epochal work placed them in their proper category are the neurocytomas or neuroblastomas. The confused terminology of this group will be discussed later.

As previously stated, these tumors are as widely distributed in the body as the sympathetic nervous system itself but by far the greater number are to be found in the adrenal. Lewis and Geschickter studied 40 neuro-

From the Departments of Pathology and Surgery University of Michigan Hospital, Ann Arbor Michigan.

blastomas and found that 33 of them were in the medulla of the suprarenal gland, or in sympathetic ganglions adjacent to the medulla. Scott and Palmer reviewed the literature up to 1932 and found only 37 reported cases of sympathetic blastomatous tumors other than those in the adrenal medulla. Shultz in 1926 reported 53 cases of gangli-neuroma not in the adrenal. The number of these cases found in the chest is not stated by either author. Loretz's case in 1870 is the first thoracic sympathetic tumor reported. Reid lists 3 cases of intrathoracic neuroblastoma and 6 of ganglioneuroma reported up to 1928. Bigler and Hoyne reporting 1 case of their own in 1934, reviewed the literature up to that time and found 11 reported cases in the thorax out of a total of 164 cases of ganglioneuroma in various situations. James and Curtis found 33 reported cases up to 1941 and Skinner reporting 1 case in 1943 cites 37 in the literature. Wahl and Robinson state that up to 1943 only 13 cases of thoracic neuroblastoma have been reported out of about 200 cases in the entire literature. Paraganglioma are rare in adults and rarer in the chest, only 2 cases of thoracic origin having been recorded although Wahl and Robinson report an interesting case of a mediastinal neuroblastoma containing pheochromoblastomatous elements.

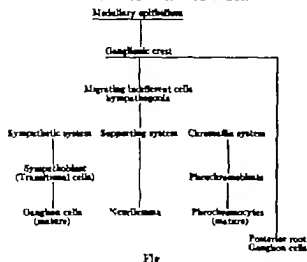

EMBRYOLOGY

A thorough understanding of sympathetic nerve tumors is dependent on a knowledge of the embryology of the sympathetic nervous system. According to Jordan the peripheral nervous system comprises nerves and ganglia outside the central nervous system. It includes (1) the cerebrospinal nerves and (2) the sympathetic nervous system. Constituent nerve fibers include both myelinated and unmyelinated varieties. The sympathetic ganglia of both the trunk and head arise from cells which migrate from the neural tube to their definitive positions. In the trunk region the ganglion cells migrate before the formation of definitive nerve fibers and during migration the cells are in an indifferent stage only later developing into either neuroblasts or support ing elements. It is well known that this

migration takes place at an early period of embryological development. In addition to the sympathetic neurocytes, the sympathetic primordium is also the progenitor of the chromaffin (pheochromic) cells. In the early stages of development the two can not be distinguished from each other. The chromaffin cells are characteristic of the paraganglia the medulla of the suprarenal and the carotid body, although their presence in the latter is denied by some. The paraganglia are formed from groups of these cells which have migrated along the entire sympathetic system. Some migrate to the dorsal surface of sympathetic ganglia where they form small rounded masses which become lodged in depressions in the ganglia. Other cells migrate to the kidneys, uterus, liver and testes while still others come to rest on the ventral surface of the abdominal sympathetic plexuses and differentiate into larger chromaffin bodies. The largest of these are the organs of Zuckerkandl which develop in the connective tissue along the sides of the aorta near the bifurcation. The chromaffin cells of the suprarenal medulla pass laterally from the celiac sympathetic plexus until they come in contact with the cortical cells which have developed from the celomic epithelium. The medullary cells then grow into the mass of cortical cells then growth beginning at about the 12 millimeter stage and continuing until after birth. According to Poll the development of ganglion cells from sympathogonia continues until the tenth year and thus may be a factor in the development of neoplastic conditions of the sympathetic system. These peripherally migrating nerve cells may come to rest almost anywhere in the body and are capable of proliferating and forming tumors at a later date in life.

Experimentally the origin of the sympathetic system has been proved by Harrison's historic work and confirmed by Van Campenbout. They showed that the removal of the entire neural crest from embryo Rana pipiens will result in total failure of development of the spinal and sympathetic ganglions throughout the trunk region. The motor neurons develop normally but are sheathless the chromaffin apparatus of the adrenal gland

EMBRYOLOGICAL DEVELOPMENT OF SYMPATHETIC NERVOUS SYSTEM

does not develop and there are no sympathetic nerve elements in the wall of the digestive tube.

A critical examination of the sympathetic primordia shows these elements to be totally undifferentiated. They are spherical in shape and possess round chromatin rich nuclei surrounded by scant cytoplasm. These cells have often been described as lymphoid cells and it is this lymphoid characteristic which undoubtedly led early observers to describe tumors composed of these cells as small round cell sarcomas or lymphosarcomas. Even at this early stage according to Bielschowsky these sympathogonia or undifferentiated neurocytes possess very delicate fibrils which are not as yet demonstrable by the silver staining method. Passing along to the next stage of maturation sympathogonia develop into sympathoblasts which are somewhat larger than the former possess a clearer almost vesicular nucleus and a somewhat larger protoplasmic body. In part they produce axones which may be demonstrated by the silver method in the form of fine threads and may be traced over long distances. The final stage of maturation is represented by the sympathetic ganglion cells in which the nucleus-plasma relation is largely in favor of the cell body. The cells possess predominantly a multipolar form and exhibit a varied manner of branching of their processes. They contain intra-

cellular fibrils and chromophile Nissl clumps. These nerve cells are enclosed in a connective tissue capsule and are surrounded by gliogenic satellites.

The embryogenic factor of importance in the understanding of the histopathological findings in sympathetic neoplasms is the rôle played by the sympathogonia. They have been assigned a place in the scheme of development comparable to the rôle of the medulloblast in the developing central nervous system. Schaper was the first to hypothesize indifferent cells, derived from the medullary epithelium, bipotential in their possibilities, and developing into either spongioblasts or neuroblasts. While many workers deny the existence of the medulloblast His accepted these cells but he did not believe them to be bipotential. He believed, rather that each cell was unipotent and was predestined from the beginning to become a spongioblast or a neuroblast. Bailey and Cushing believed that Schaper's hypothesis was necessary for a proper comprehension of the normal histogenesis of the brain of malformations of the brain and of brain tumors. Having been generally accepted this theory is likewise essential to a proper understanding of the developing sympathetic nervous system and its abnormalities. Sympathogonia, then, are generally considered as indifferent cells, prioripotent in their possibilities and the mother cells of (a) sympathoblasts and sympathetic ganglion cells (b) the chromaffin (pheochromic) cell structures which are the pheochromocytes of the adrenal medulla, the paraganglionic bodies and other structures and (c) the immature glial cells of the sympathetic nervous system, the astroblasts, which ripen into mature supporting units, the astrocytes. The genetic elements comprising the sympathetic nervous system are expressed schematically in Figure 1.

Martius in 1913 described a tumor in which he found both a high degree of differentiation of the fibrillae and the presence of many cells that corresponded to Poll's sympathoblasts. He called this tumor a sympathoblastoma and looked upon it as affording the missing link between ganglioneuroma and the malignant neuroblastoma.

CLASSIFICATION

Inasmuch as it has been demonstrated that the sympathetic nervous system is developed by a progressive growth of and a differentiation from the pluripotential mother cells, the sympathogonia, it is to be expected that tumors arising during the process of differentiation may contain cells in varying degrees of maturity. This naturally produces new growths difficult of classification, as the tumors rarely contain a single cell type. Various transitions between different forms have been reported and two or three types may be present in one tumor. Numerous classifications have been offered and even a casual review of what has been written on the subject serves to convince the reader of the confusion which exists. Wahl in 1914 Dunn in 1914 1915 Lehman in 1922 Symmers in 1936 and others have classified cases as neuroblastomas ganglioneuromas and chromaffinomas. Von Fischer in 1922 classified the group according to degree of differentiation. Scott and Palmer in 1932 base their classification on the plan proposed by Bailey and Cushing for tumors of the central nervous system. Bielschowsky believes that a simple classification is best and that any attempt to subdivide on a basis of degree of immaturity only adds to the confusion and his classification is the simplest one found. Robertson in 1915 correlated the terms used by previous authors. 'Neurocytoma' (Marchand) = neuroblastoma (Wright) = 'sympathicoblastoma' or 'ganglioma embryonale sympathicum' (Pick) = 'sympathogonioma' (Kohler) = 'sympathicoblastoma' (Robertson). Bailey and Cushing prefer the term 'sympathicoblast' for the primitive pluripotential cell before it has taken on the characteristics of a unipolar neuroblast and they use the term 'sympathicoblastoma' instead of 'neuroblastoma' for all tumors in which the cellular elements are of the undifferentiated type. They feel that 'sympathicoblastoma' more definitely places these tumors because the term 'neuroblastoma' is used also to describe certain cerebral neoplasms. Further all the primitive cells are not potential neuroblasts since some differentiate into chromaffin cells. On this basis Blacklock classifies all cases, exclusive of the

CLASSIFICATION OF SYMPATHETIC TUMORS (BIELSCHOWSKY)

Fig. 3

chromaffinomas, into sympathicoblastomas (all malignant) and ganglioneuromas (generally simple and benign). The former he subdivides into (1) undifferentiated (composed only of sympathogonia) and (2) differentiated. The differentiated he again subdivides into those which are composed of sympathogonia and sympathoblasts and those containing ganglion cells in addition to the primitive cells. These he terms ganglioma sympathicoblastoma. From a practical clinical and pathological point of view Bielschowsky's simple classification is appealing. Schematically it is represented in Figure 2. Bielschowsky makes no attempt to subdivide the tumors according to the various degrees of differentiation as is done by some authors. As has been repeatedly stressed, these tumors are composed of more than one cell type and a thorough understanding of the embryology with the designation of the neoplasm according to the predominant type of cell present, should serve to give one a clear picture of the pathological process.

DISCUSSION

A discussion of sympathetic nerve tumors on a basis of any of the various classifications available is very difficult. However from a review of all available descriptions of the microscopic appearance of the reported tumors I believe that the names neuroblastoma, sympathoblastoma, and sympathicoblastoma have been used interchangeably to designate the immature type of tumor. Usually no attempt has been made to separate these immature tumors into those composed entirely or predominantly of sympathogonia (sympathogonioma), and those in which the

TABLE L.—INCIDENCE ACCORDING TO AGE AND SEX—63 REPORTED CASES

*Not stated—4 cases

**Not stated—0 cases

sympathoblast (sympathoblastoma) in various degrees of maturity is the predominant cell. The present discussion follows Biel schowsky's simple classification (Fig. 2).

Sympathogonioma. As is to be expected the sympathogoniomas are very malignant. Found most commonly as a primary growth in one or both adrenals, their occurrence in the chest is rare, Sailer and Andrus having reported the only cases. However taking the factors mentioned in the preceding paragraph into consideration one is justified in assuming that other sympathogoniomas are present in the group reported as neuroblastoma or sympathoblastoma. The case reported by Stariz and Abrams is an example. This was a 3 year old child who died and at autopsy extensive metastases to the lymph nodes and bones were found. Microscopically the tumor was composed almost entirely of small round cells with scant cytoplasm, typically sympathogonia. Because of their highly malignant nature they are found most commonly in the newborn and in youth rarely in adults. Paradoxically enough, Sailer's case was in a woman of 65 years of age.

Sympathogonioma are extremely cellular being composed of the closely packed lymphoid type of cell previously described. Very little supporting structure is seen. There is a tendency to rosette formation, Lewis and Geschickter having found rosettes in one-third of their cases and Wahl reporting them in one-half of the cases studied by him. Metastases usually occur early and are widespread, being found most frequently in the

lymph nodes long bones, skull brain, and liver.

Sympathoblastoma. Sympathoblastomas, differing only in that they represent greater maturity are somewhat less malignant and usually are found at a somewhat older age. Scott and Palmer reporting on 13 sympathetic tumors other than those in the adrenal gland found that 5 or 38 per cent, were in children 3 years old or younger as compared to 11 or 58 per cent, of 19 sympathogoniomas in the same age group. Intrathoracic sympathoblastomas are rare occurring in only 16 of the 63 cases of sympathetic nerve tumors found recorded to date an incidence of 25.5 per cent. This includes the case of Wahl and Robinson which contained pheochromoblastomatous elements and Cushing and Wollbach's case which was of the dumbbell type the intrathoracic portion being a sympathoblastoma and the intra-spinal portion (removed 10 years after the intrathoracic operation) a ganglioneuroma. The age limits were from 12 weeks to 48 years, 12 of the 16 cases or 75 per cent occurring in children under 10 years of age.

Blacklock states that no tumor composed only of sympathoblasts has yet been reported. While these cells usually predominate in the over-all picture sympathetic ganglion cells in all degrees of differentiation are encountered. Sympathogonia, sympathoblasts, immature ganglion cells, and mature ganglion cells may be present in one section. On the other hand, sections from different parts of the same tumor may present only one cell type and

unless blocks are cut from various parts and studied an entirely erroneous diagnosis may be made. Not as cellular as the sympathogonia, these tumors may contain large numbers of nerve fibrils. Differential stains such as silver impregnation, chrome salts and connective tissue stains are often necessary for complete classification. Metastasizing much more slowly than the sympathogonioma, they are more apt to show local invasive tendencies. Their metastasizing tendencies, however, are as varied as their microscopic picture.

Ganglioneuroma. Passing on to the mature tumors we have the ganglioneuroma. In these the neurocytic elements have differentiated into ganglion cells rich in plasma. Contrary to the opinion expressed by Bohrer and Lincoln this tumor is far from rare among children. Shultz reported 53 cases of ganglioneuroma not in the adrenal gland. Twenty-four were in adults, 21 in children and in 8 the age was not stated. In the intrathoracic cases the age varied from 1 to 73 years. 21 out of 43 cases or 48.8 per cent, being 10 years of age or younger and 29 or 67.4 per cent, under 20. In 3 additional cases the age is not given although one is stated to be a child. In none of these tumors, however, can age *per se* be said to be of great importance as all are due to embryonic rests, the age given representing only the age at which they are discovered. Sex also is unimportant, 12 of the cases being in females, 11 in males and in 6 the sex was not stated (Table 1).

Ganglioneuromas vary in size, the reported tumors ranging from that of a hen's egg to that of a child's head. Usually of firm consistency and well encapsulated, degenerative changes may give the tumor a soft feel beneath a firm outer shell. The cut surface may show lobulation and its color varies according to the degree of vascularity. Usually they are relatively avascular and present a grayish white to gray glistening appearance. Microscopically the picture is usually one of rather coarsely arranged fibrous tissue mixed with strands of medullated and nonmedullated nerve fibers, the latter predominating as a rule. Multipolar ganglion cells in varying numbers are found scattered throughout

Some areas may be very cellular while in others only an occasional ganglion cell is seen. These areas vary not only in different tumors, but in different parts of the same tumor. Not infrequently multinucleated ganglion cells are seen indicating an element of immaturity. In addition, tumors are encountered in which varying numbers of ganglion cells are present in a growth which otherwise has all the criteria of a fibrous tissue growth. To these the name ganglion neurofibroma or ganglionated neurofibroma has been given by some pathologists. Cases 3, 4, 6 and 7, reported in this article represent this type.

Usually considered as benign tumors malignant ganglioneuromas have been reported. These are due to an abundant intermixture of immature ganglion cells and have been designated as ganglioneuroblastoma.

Chromaffin tumors. Chromaffin tumors which Lewis and Geschickter consider the most common tumors of the sympathetic system are exceedingly rare within the thorax, only 2 cases having been reported, that of Miller in 1924 and Phillip's case in 1940. The case of Wahl and Robinson previously mentioned did contain chromaffin elements although the authors classified it as a sympathoblastoma. Their most distinguishing feature is, of course, their affinity for chrome salts. The large polyhedral cells in a richly vascularized fibrous tissue stroma show a granular cytoplasm and a large nucleolus usually containing one large nucleolus. Sections fixed in Orth's solution which contains potassium dichromate stain the cytoplasmic granules a golden yellow.

Dumbbell tumors. Tumors which present both in the chest and in the spinal canal, the so-called dumbbell or hourglass tumors, have been described. They are of fairly frequent occurrence, particularly among the ganglioneuromas. While an intrathoracic growth may conceivably grow into one or more of the vertebral foramina, I believe that these tumors are more accurately accounted for on an embryological basis, either from an embryonic rest of the migrating indifferent cells or from the ganglionic elements of an intercostal nerve. Quite frequently it is the pressure of the spinal segment of the tumor

on the cord which brings the condition to the attention of the patient. They are found more frequently in children. Eden in his paper devoted to this type of tumor reports an interesting case of a man 23 years of age whose first symptoms dated back to age 5 when a radiographic opacity in the chest had been diagnosed as an irreducible sarcoma of the spine. During the intervening 18 years, he had been free of symptoms but finally presented himself for treatment because of leg weakness and difficulty in urinating the same symptoms which had called attention to the tumor many years before. At operation the tumor was found to be a ganglioneuroma, dumbbell type.

Unusual types. Martius (quoted by Dunn) in 1913 described a case in which a malignant neuroblastoma was removed surgically from the lower part of the neck, and, on subsequent postmortem examination another part of the same tumor in the uppermost part of the thorax was found to be a ganglioneuroma. Furthermore Suzuki 1910 Hedinger 1911 and Wahl 1914 have reported cases in which sympathogonia, ganglion cells and chromaffin cells were all present in the same growth. Wahl and Craig have also found that these tumors may be multicentric. While usually of the same type, all three types (neuroblastoma, ganglioneuroma, and paraganglioma) may be present, occurring independently of each other. They report a case of a 28 year old man in whom three separate growths were found (1) a ganglioneuroma of the sigmoid colon (2) a neuroblastoma in the pelvis and (3) a ganglioneuroblastoma in another part of the pelvis. The only multicentric tumor involving the chest is that reported by Bigler and Hoyne, a mediastinal ganglioneuroma with another located under the right clavicle.

Neurofibromas. Finally one must not lose sight of the fact that any of the intrathoracic neurogenic tumors may have their origin from the sympathetic nervous system. In speaking of sympathetic nerve tumors, one instinctively thinks only of the immature and mature ganglion cell tumors already described. However reference to Figure 1 clearly indicates that all the neurogenic elements found in the neurofibromas, schwannomas, etc. are de-

rived from the ganglionic crest. In addition to this, even though the neoplasm may grossly appear to originate from an intercostal nerve, it must be remembered that intercostal nerves are derived partly from the ganglions of the posterior roots, which ganglions arise from the medullary epithelium by way of the neural crest. There are two schools of thought regarding the origin of neurofibromas, one group who note the presence of collagen and reticulum fibers and regard them as true mesoblastic fibromas, and the second group who trace all the tumors to neural elements, especially the Schwann cells, endoneurium and the lamellar sheath. In either case they may be derived from the sympathetic system and thus subject to classification under this heading. In this connection, a recent case report by Blades and Dugan is of interest. Two neurofibromas were found on the upper sympathetic chain within the thorax and one on the left vagus below the recurrent nerve. In addition, this patient had *café au lait spots* in both axillae and on the chest, typical stigma of von Recklinghausen's neurofibromatosis. Removal was without incident. In spite of the definite possibility of their sympathetic origin, no classification has yet been offered which makes provision for the inclusion of this large group of tumors. In fact, they are not usually considered as sympathetic nerve tumors. The increased incidence of the removal of intrathoracic neurogenic neoplasms will undoubtedly stimulate further study of these growths and lead to a more accurate classification.

CASE REPORTS

Seven cases of intrathoracic sympathetic nerve tumors have been found in the records of the University Hospital and they are reported somewhat in detail here.

CASE 1. E. L. H. No. 372334, a 7 year old school girl, was admitted to the University Hospital on October 24, 1935. Her chief complaint was pain in the left side of the chest. The pain began about 1 1/2 years previously and had increased gradually up to the time of admission. For the past year there had been shortness of breath on exertion and she had failed to gain weight. One month previously she had had an unexplained period of fever up to 103 degrees and an x ray film of the chest disclosed a tumor in the left hemithorax. Essential physical findings were heart displaced to right, the right border of

cardiac dullness being 1 centimeter medial to the right nipple line and the left border of cardiac dullness shaded into the flatness of the lower part of the left chest. Heart sounds were normal. The left chest was flat to percussion below the left second rib anteriorly the fourth rib in the axilla, and the fifth and sixth posteriorly. Below this line breath sounds were absent. Tactile and vocal fremitus were absent. In the abdomen fullness was demonstrated in the left upper quadrant and the spleen could be palpated below what appeared to be a tumor mass. The Kahn reaction and all routine laboratory tests were within normal limits. The vital capacity was 675 cubic centimeters coagulation time 6 minutes. X-ray examination revealed a gross tumor mass in the left upper abdomen and lower thorax apparently displacing the spleen and kidney down and the diaphragm up. The position of the mass was predominantly posterior. There was no evidence of skeletal involvement. Deep x-ray therapy had been given without benefit elsewhere before admission. Operation was performed on October 28 1933 by Dr. John Alexander. Removal of a firm tumor which was retropleural and attached to the entire anterior surface of the diaphragm and to the entire posterior diameter of the mediastinum except in the far anterior portion. Only moderate bleeding occurred all of which was relatively easy to control. Patient withstood the operative procedure well but died 1 hour postoperatively of hemorrhage.

Pathological report No. 2902 AN. A large encapsulated tumor 17 by 12 by 5 centimeters, weighing 1150 grams. Smooth surface lobulated on one side. On cut section surface is yellow gray. Microscopic diagnosis ganglioneuroma.

CASE 2 B. L. No. 472537 a white girl, aged 8 years, was admitted to the University Hospital on January 8 1941. This patient apparently had no symptoms referable to the chest. She was seen elsewhere in December 1940, with the complaint that during the past 4 years the feet had become deformed and interfered with walking. She had a pes equinus deformity. In the course of her check up examination a chest x-ray film was made and showed a complete opacity of the left hemithorax with displacement of the heart and mediastinum to the right. In the standard films, it was impossible to differentiate between a massive tumor and fluid. Later grid films showed a well circumscribed encapsulated mass in the posterior portion of the left hemithorax. There appeared to be numerous flecks of calcium within the mass. At fluoroscopy it was felt that the mass contained fluid and a thoracentesis was done but no fluid was obtained. Following the thoracentesis there was a sharp rise in temperature to 102 degrees and the pulse rate reached 160. Two days later an exploratory thoracotomy was done and the biopsy material obtained revealed a ganglioneuroma. The child was then sent to the University Hospital for removal of the tumor. The past history was noncontributory except for the fact that the child had had measles with a com-

plicating pneumonia 2 years previously. She was never really well after this, being nervous and irritable and had a poor appetite. The physical examination showed only a poorly nourished girl of 8 years with a pes equinus deformity of both feet. No other abnormalities were noted except in the chest where the findings were compatible with the lesion revealed by the x-ray examination. Routine laboratory tests were within normal limits. The Kahn test was negative.

Operation was performed February 14 1941 by Dr. Cameron Haight. The chest was opened through the usual posterolateral incision. The tumor mass exposed was a very firm one. In the scapular line the subjacent tumor was adherent to the parietal pleura but in the anterior axillary line a free pleural space was present. The anterior portion of the tumor was not adherent to the lung which was crowded into the anterior portion of the pleural cavity. The sixth intercostal nerve entered the capsule. The tumor extended from the third rib posteriorly to the diaphragm. Deep fingerlike processes of tumor extended into the eighth ninth and tenth intercostal spaces adjacent to the spine. The mass was removed by blunt and sharp dissection and at about the time it was removed respirations suddenly ceased. Only a limited autopsy was obtainable and from this it was impossible to determine if the spinal canal had been invaded by the growth. No regional metastases were present. Grossly this was a large oval-shaped encapsulated tumor presenting irregular nodes on the surface and on section a uniform waxy and fibrous, yellowish tissue. Its weight was 595 grams and it measured 16 by 10 by 6½ centimeters.

Microscopic examination pathological report No. 4305 AS. The tumor is made up of countless large ganglion cells which frequently contain two or more nuclei and numerous bundles of peripheral nerves lying in a dense connective tissue stroma and showing areas of secondary calcification and perivascular inflammation. Diagnosis peripheral ganglioneuroma.

This was a typical ganglioneuroma showing a relative amount of immaturity as evidenced by the frequent multinucleated ganglion cells seen.

CASE 3 T. O. No. 486332 white schoolboy aged 11 years was admitted July 31 1941. This boy had no symptoms either past or present as a result of the neoplasm present in his chest. A routine tuberculin test at school in May 1941 was positive and for that reason a chest x-ray film was made. This film showed the presence of a tumor mass in the left hemithorax. On admission, physical examination was negative except for the chest. There were diminished breath sounds at the left apex, extending down to the second anterior rib. There was impaired resonance but normal fremitus over this area. No rales were heard. Posteriorly there was dullness

diminished breath sounds, and whispered voice sounds down to the sixth rib. The blood Kahn reaction was negative and all routine laboratory tests were within normal limits. X ray examination of the chest showed a rounded mass in the upper portion of the left hemithorax extending as low as the anterior portion of the third interspace. Some erosion of the posterior portion of the third rib was visualized. Oblique and lateral views showed the large mass to lie far posteriorly and adjacent to the vertebral column.

Operation was performed on August 1, 1941 by Dr. John Alexander. The approach was posterolateral through the bed of the fourth rib with resection of about 6 centimeters of the third rib. A slightly soft and completely encapsulated neoplasm was found in the costovertebral gutter extending from below the dome of the pleural cavity to the level of the fifth posterior intercostal space. After dividing the parietal pleura around the base of the tumor it was readily removed by blunt dissection, the removal including a lobulation which projected into the mediastinum. The pedicle of the tumor appeared to be at the level of the third intravertebral foramen and the third and fourth transverse processes were removed to expose this foramen. The tumor was seen to traverse this foramen, which was larger than normal. Portions of the lamina were removed and at a depth of 1.5 centimeters in the foramen, the tumor was seen to taper off to a point and was removed completely. Recovery was uneventful and the patient left the hospital on the sixteenth postoperative day. He has remained entirely well to date.

Pathological report, No. 666 AT. Microscopically routine hematoxylin and eosin stained slides show a stroma having the appearance of a neurofibroma and containing large numbers of typical ganglion cells. Diagnosis, ganglionated neurofibroma.

This was another case of a rather large tumor which was symptomless and discovered only accidentally. It was almost a dumbbell type extending for a short distance into the intervertebral foramen.

CASE 4. K. T. No. 536736 white boy aged 13 years, was admitted December 5, 1933. This patient had no chest symptoms. A short time before this admission he had had a fall and x ray films of his shoulder were made. These revealed an intra-thoracic neoplasm and he was referred to the University Hospital for its removal. The rest of the history is noncontributory except for the presence of a long standing and very extensive eczema. Physical examination showed very little. There were some palpable enlarged lymph nodes in the neck and both axillae. A diffuse dry scaly eczema was noted over the greater part of the body and extremities. There were dullness to percussion and diminished breath sounds over the upper left chest both anteriorly and posteriorly. The rest of the examination was nega-

tive. The blood Kahn reaction was negative and other routine laboratory examinations were within normal limits. X ray examination of the chest revealed a fairly extensive homogeneous obscuration of the upper portion of the left hemithorax, more marked in its median aspect. Films of the dorsal spine revealed extensive erosion of the upper dorsal vertebral bodies. The erosion began at the level of second dorsal vertebra and extended downwards as far as the sixth dorsal vertebra. The left lateral and posterior aspects of the vertebral bodies were involved and the abnormality was in the form of scalloping of the margins of these bodies. There appeared to be associated widening of the anteroposterior diameter of the spinal canal in the region of the vertebral erosion and there was also associated erosion of the vertebral and posterior portions of the third, fourth and fifth ribs.

Operation was performed December 10, 1943 by Dr. John Alexander. A posterior approach was used with the incision extending from the second rib over the sacrospinalis muscle downward to the seventh rib and laterally beyond the inferior angle of the scapula. On the posterior surface of the sacrospinalis muscle from the level of the third to the fifth posterior ribs a neurofibromatous lesion was visible. This lesion in the muscle was completely removed, together with the adjacent muscle tissue. This had a vertical length of approximately 4 centimeters and a horizontal width of approximately 3 centimeters. This was later seen to have arisen from the main tumor mass at the level of the extreme posterior third intercostal space. It was necessary to remove, subperiosteally, the posterior 10 centimeters of the fourth, fifth, and sixth ribs. Also the head and neck of the fourth rib were removed so as to give maximum exposure of the third and fourth intervertebral foramen where the tumor tissue was applied singly to the foramen. The tumor appeared to be attached to the third, fourth, fifth, and sixth intercostal nerves at their emergence from the intervertebral foramina. By blunt and sharp dissection the tumor was finally removed from its bed. Usual closure without drainage. The postoperative period was rather stormy and a left-sided empyema had to be drained on the fifteenth day. The ultimate recovery was complete however and the present condition is excellent.

Pathological report No. 2465 AV. Hematoxylin and eosin stain. Sections show large fragments of a neurofibroma. Some of the stroma is edematous and much of it shows early hyaline change. In one section numerous ganglion cells are scattered through the neurofibromatous elements. There was no invasion of the attached muscle and bone fragments. Diagnosis, ganglionated neurofibroma.

CASE 5. J. S. No. 551083 white male, aged 39 years, was admitted to the University Hospital July 6, 1944. The chief complaint was extreme dyspnea. In March, 1944, he began to have pain in the right chest which persisted to date. In addition there were cough and fever the temperature rising to 103

degrees. Cough was productive and the sputum was streaked with bright red blood. The fever lasted for 2 weeks and then returned to normal. The condition was diagnosed as pneumonia. Although the other symptoms subsided the pain remained and an x ray examination of the chest was made. It revealed a "tumor of the right lung. Eleven deep x ray therapy treatments were given without effect. The pain gradually became more severe. It was both dull and sharp. Worse in the right chest it radiated at times to the right arm. The amount of sputum increased until it totaled about one-half cupful a day. It was purulent but not foul. For the week before admission there had been some edema of the feet and ankles. Because of the pain and dyspnea, the patient could not lie down. On admission he was in extreme dyspnea and mildly cyanotic. During the 4 days before operation he was kept constantly on intranasal oxygen. The Kahn reaction was negative and all routine laboratory procedures were within normal limits.

Operation was performed by Dr. John Alexander on July 10, 1944. When the chest was opened a large tumor was found filling the upper half of the right hemithorax. Its size was estimated as about 12 by 12 by 12 centimeters. The right lung was displaced downward and the upper mediastinum to the left. The tumor was "frozen" to the mediastinum and to the spine. Removal was impossible. It was impossible to determine whether the mass was merely "frozen" to the mediastinum and spine or whether it was infiltrating these structures. The inside of the tumor was completely degenerated. The degenerated inner portion of the mass was evacuated and about 52 per cent of the wall was removed in order to relieve the pressure on the trachea and great vessels of the upper mediastinum. Dyspnea was greatly improved. Recovery was uneventful there being one thoracentesis for the removal of a few hundred cubic centimeters of fluid. He was discharged on the thirteenth postoperative day. The subsequent course was downhill and death was reported to have occurred within a few months. There was no autopsy.

Pathological diagnosis No. 100 AW Sympathoblastoma

CASE 6 J. L. N. No. 562795 white schoolboy aged 16 years had neoplasm producing no symptoms. The tumor was discovered when a chest x ray film was taken at school in a routine tuberculosis survey. He was then referred to the University for surgical treatment. The past history was noncontributory. The physical examination was negative except for the chest. Posteriorly there was increasing dullness to flatness from the second rib down to the seventh. Decreased breath sounds over this same area. The blood Kahn reaction was negative and all routine laboratory tests were within normal limits. A x ray examination showed a large mass which was fairly smoothly rounded anteriorly and which lay in the posterior portion of the left hemithorax and extended from the level of the third or fourth dorsal vertebra

as far down as the tenth dorsal vertebra. This mass was of homogeneous density and in lateral view it was seen to lie far posteriorly. There was considerable bony architectural change. This consisted of abnormality of the structural character of the fourth, fifth, and sixth vertebrae. There was suggestive evidence of widening of the neural canal between fifth and sixth dorsal vertebrae and definite abnormality of the left sixth and seventh ribs posteriorly. There was what appeared to be loss of vertical height of the sixth dorsal vertebra in the anteroposterior view and in the lateral view there appeared to be some loss in vertical height of fifth dorsal vertebra and possibly also of the seventh. In addition the intervertebral disc space between the fifth and sixth dorsal vertebrae was not easily identified and the pedicle on the left of the fifth dorsal vertebra appeared to be absent. In part, the changes appeared to be due to erosion, probably due to pressure, and in part they may be due to congenital malformation. The changes did not suggest invasion of the vertebra by neoplasm.

Operation was performed by Dr. Cameron Haight on February 10, 1945. The approach to the tumor was posterolateral through the bed of the resected fifth rib. The large tumor mass was partially adherent to the parietal pleura and it occupied the posterior half of the chest at the level of the resected rib. The lung was crowded forward by the tumor. The tumor was of a firm consistency and had a yellow color. On its surface were scattered areas of organized fibrin. The tumor was removed by blunt and sharp dissection. During its removal it was seen that the sympathetic chain and the fifth and sixth intercostal nerves were all either incorporated in or attached to the mass. They were removed with the mass. After the removal of the tumor it was seen that a nodule projecting from the surface of the tumor had caused an erosion of the fifth intervertebral foramen and had exposed the epidural veins over an area of about 1.5 centimeters. Recovery was uneventful and the patient left the hospital on the thirteenth postoperative day.

Pathological report, No. 3853 AW. The specimen consisted of a grapefruit sized, well encapsulated mass which on section had a firm, whitish appearance. Microscopic, a large neurofibroma with a few ganglion cells. Diagnosis: ganglionated neurofibroma.

CASE 7 D. S. No. 564033 was admitted February 14, 1945. This 2 year old boy was seen first in the Department of Pediatrics. He had been in perfectly normal health until 4 weeks before admission at which time the mother noticed that he dragged his left leg. Soon afterward he began dragging his right leg also and then ceased to walk entirely. This condition progressed rather rapidly until he soon was unable to sit up but he complained of no pain. The mother noticed however that there was increased irritability. There was no incontinence of urine or feces. Two weeks before admission he was seen elsewhere and a diagnosis of spinal cord tumor

was made. He was then referred to the University Hospital for treatment. Physical examination revealed a well developed white boy who did not appear acutely ill but who was unable to walk or sit up. All findings, including funduscopic examination of the eyes were negative except the following. Extremities showed bilateral paralysis of the legs. The patella reflexes were greatly hyperactive. The right leg offered some resistance when bent. The ankles were quite stiff. The left leg responded markedly when the Babinski test was tried. The right responded with spreading of all toes on trial of the same test. There was no diminution of pain sense. The blood Kahn test was negative as was the tuberculin test. All other routine laboratory examinations showed results within normal limits. X ray examination of the chest revealed a huge solitary well defined tumor occupying the left upper chest with displacement of the mediastinum to the right. Finely dispersed calcification was present throughout the mass. Detail films of the spine showed no abnormality.

A lumbar puncture was done on the day after admission and bloody spinal fluid was obtained. There was evidence of a partial block.

The child was seen in consultation by the departments of neurology, neurosurgery and thoracic surgery. It was agreed that the first attack should be directed toward removal of the spinal cord pressure, after which, removal of the intrathoracic portion of the mass would be attempted. The child seemed to remain perfectly well until February 16 at which time he developed a cough and evidence of an acute bronchitis. In spite of vigorous treatment he developed increasing respiratory difficulty and died on February 27.

Autopsy report. Only the pertinent facts pertaining to the neoplasm will be recorded here. All other findings were essentially normal and no evidence of metastases was found. "In the left pleural cavity is a neoplasm measuring 10 centimeters in diameter. It is round. There are numerous widely dilated blood vessels coursing over the surface of this neoplasm. The surface is a dull reddish-purple in color and glistening. It is firmly attached at the upper pole to the apex of the left pleural cavity by firm fibrous adhesions. It somewhat compresses the left subclavian artery which courses over its superior surface. There are several pale, white, oval bodies attached to the superior surface which appear to be lymph nodes infiltrated by neoplasm. Posteriorly the neoplasm is attached by fibrous adhesions to the second, third and fourth ribs and so firmly at the root of the second and third that portions of these ribs were removed in order to facilitate removal of the neoplasm. Medially it is attached to the first, second, third, and fourth dorsal vertebrae, again by firm fibrous adhesions. These vertebral bodies were removed with the tumor and, although the tumor was perfectly encapsulated in other areas, it appears to have invaded the spinal canal at the level of the second and third spinal foramina, extending along

the spinal canal for a distance of about 5 centimeters and forming a mass within the canal approximately 1.5 by 1 centimeter in diameter which somewhat compresses the cord, although it does not appear to have infiltrated it. On cut section of the tumor the cut surface is a dull white in color and is moderately firm. There is a medial area which appears somewhat whorled is firm in consistency and is a grayish-white in color." Weight 180 grams.

Microscopic examination revealed many connective tissue fibers showing whorled areas, numerous scattered ganglion cells, areas of calcification. The portion which invaded the spinal canal has a similar appearance. The nodules on the superior surface of the tumor are similar to the neoplasm, with no evidence that they arose in lymph nodes. Diagnosis, ganglionated neurofibroma.

This case appears to have been a rather rapidly growing ganglioneuroma of the dumb-bell type causing paralysis and then death from spinal cord pressure.

PILONIDAL CYST

Analysis of 100 Consecutive Cases Emphasizing Treatment by Radical Excision Primary Closure and Penicillin Therapy

LEO C. LARKIN M.D., Lieutenant Commander M.C., U.S.N.R., Oak Park, Illinois

IT is the purpose of this paper to present a series of 100 consecutive cases of patients with pilonidal cyst (sacrococcygeal cyst teratoma U S Navy nomenclature) operated upon by the author between January 15 1945 and July 30 1945. A new previously unreported method of treatment has been used with results that are believed to be unusual.

Eighty-seven of these patients were operated upon by a technique of radical dissection and primary closure to be described and the plentiful use of intramuscular penicillin therapy. In 75 cases, healing occurred *per primam* by the 7th postoperative day. The series includes 34 patients with recurrences who had previously been operated upon elsewhere and 66 patients who had not been operated upon prior to admission to this proctology service. Of this latter subgroup which proved most amenable to radical excision and primary closure, in 60 cases out of 66 or 90.9 per cent healing was firm by the 7th postoperative day.

The technique employed consists of four principal features:

1. Careful preoperative preparation and the routine use of preoperative and postoperative penicillin therapy.

2. Excision of a minimum strip of skin sufficient only to include the ostia of the cyst undermining of the skin, removal of the cyst *en bloc* and the radical excision of the surrounding fat thus exposing the sacrococcygeal fascia and the gluteal fascia bilaterally to assure removal of all cystic tissue.

3. Accurate reapposition of the skin and use of wire through-and-through sutures in-

serted to the outer limits of the wound and underneath the sacrococcygeal fascia. The latter sutures are twisted over rolled gauze dressings and sponge rubber thoroughly to obliterate dead space.

4. Avoidance of the use of any drain or permanent suture in the wound and the removal of all sutures on the 7th postoperative day leaving no foreign body in the wound, thus allowing for a minimum of scar tissue and the restoration of the normal intergluteal fold, without skin tension.

For the sake of presentation and review of cases, the series is divided into three subgroups, the criterion for which was, on admission and at operation the feasibility of primary closure in each case as determined by the condition of the skin overlying the cyst. That is, whether it was intact except for the embryologic ostia (Subgroup 1) scarred by previous operative procedures and containing artificial ostia but not unduly sacrificed (Subgroup 2) or markedly depleted, scarred, and stretched by previous block excision (Subgroup 3).

In Subgroup 1 consisting of all the patients (66) who had not been previously operated upon and who were treated by primary closure healing *per primam* occurred in 60 cases, or 90.9 per cent. In Subgroup 2 consisting of 21 patients who though previously operated upon appeared amenable to primary closure successful primary healing was obtained in 15 cases or 71 per cent. Subgroup 3 consisted of 13 patients who had been previously operated upon elsewhere two or more times. In these patients primary closure was not attempted because of the marked loss of skin and scarring present. Partial closure was carried out, as will be described in an attempt to cut down the disability time to a minimum.

This article has been released for publication by the Division of Publications of the Bureau of Medicine and Surgery of the U. S. Navy. The opinions and views set forth are those of the writer and are not to be considered as reflecting the policies of the Navy Department.

From the Department of Proctology U. S. Naval Hospital, Great Lakes, Ill.

Fig. 3

The surgical treatment of pilonidal disease by primary closure has always presented well known problems the most important of which are infection which frequently nullifies the results alter the best of surgical techniques and the mechanical problem of closure of the wound without tension after thorough excision of the cyst and obliteration of the dead space. The sacrococcygeal area is readily contaminated before and after surgery because of the proximity of the anus and the tendency for the skin to be moist by perspiration. The skin over the sacrococcygeal area is readily traumatized and is stretched in sitting. These factors make any postoperative wound vulnerable long after healing has taken place (27) and make it imperative that sound healing be obtained by complete obliteration of dead space by the avoidance of the use of permanent sutures which act as foreign bodies and by use of a technique which does not sacrifice the vitally needed skin overlying this area.

The needless sacrifice of skin over this area attendant upon block dissections which include the skin and its ultimate replacement in healing by inelastic scar are at least as great a cause of recurrence due to faulty healing as is the failure to obliterate dead space (22, 28).

It is an unfortunate fact that when elliptical incisions are made on either side of the intergluteal fold the maximum loss of skin occurs where it is most needed in the primary closure of the wound—in the widest diameter overlying the glutea. When primary closures are attempted after elliptical excision of the skin a flattening of the intergluteal fold results—producing a painful scar that is constantly stretched and traumatized (27) when the patient assumes the sitting position.

The technique herein presented deals with the problem of infection by adequate pre-

Fig. 4

Fig. 5

Fig 6

operative preparation atraumatic surgery and the unstinting use of penicillin therapy. The second problem that of closing dead space avoiding the loss of skin and maintaining the normal intergluteal fold is met by the following expedients:

1. The avoidance of the use of permanent sutures in the wound that may later set up foreign body reaction.

2. The closure of the dead space, accomplished by the use of multiple, deeply placed wire through-and-through sutures that encompass the wound and include the sacrococcygeal fascia. These are later tied over gauze rolls and sponge rubber to compress the wound and reappose the skin and subcutaneous tissues to the sacrococcygeal fascia. This dressing is then reinforced with an adhesive tape dressing so applied as further to facilitate the reapposition of skin and fascia and to remove any tension from the sutures.

3. The scrupulous avoidance of needless sacrifice of uninvolved skin by removing in the initial incisions, only a thin strip of skin sufficient to include the ostia of the cyst whether embryologic or artificial and any scar tissue present, resulting from previous incision and drainage or from more extensive procedures.

PREOPERATIVE PREPARATION

All patients, on admission are routinely given sitz baths three times daily and instructed to cleanse the sacral area thoroughly with soap and water. Cevitamie acid 100 milligrams daily is given by mouth. All patients

are given penicillin therapy from the day of admission—whether the condition of the cyst is quiescent infected with or without draining sinuses or abscessed. Penicillin 15,000 units, is given intramuscularly every 3 hours.

When abscesses exist or inadequately draining sinuses are present, preliminary incision and drainage are done with local 1 per cent procaine anesthesia. The incision for drainage is linear and made as close to the midline as possible to obviate later difficulties in securing intact skin flaps when complete excision of the cyst is done. Hair and other loose detritus must be removed to assure cessation of infection and drainage (128). No patient is ready for radical excision procedure until infection and induration have been thoroughly resolved by sitz baths adequate drainage penicillin and daily sterile dressings.

The night before surgery the sacrococcygeal area is carefully shaved. The patient receives two enemas one of warm water and one of glycerine and water. A third warm water enema is given in the morning 2 hours before operation. Morphine sulfate, $\frac{1}{4}$ grain, and scopolamine $\frac{1}{64}$ are administered 1 hour prior to operation. At the time of operation the operative field is again carefully scrubbed with sterile green soap and water.

OPERATIVE PROCEDURE

The technique for this primary closure emphasizes the following points:

1. Spinal anesthesia (4) is used.
2. Excision of but a narrow strip of skin is done in the midline often no wider than $\frac{1}{4}$

Fig 7

Fig 8.

Fig 9.

Fig 10.

b

inch to include the ostia of the cyst and scars from previous incision and drainage procedures (Fig 1). The skin is cleanly and accurately incised at right angles to facilitate meticulous approximation in the closure.

3. Block dissection of the cyst is accomplished down to and exposing the sacrococcygeal fascia in its entirety (Fig 2). The skin edges are then undermined with the scalpel blade partially on the flat, the lateral fatty tissue divided and the subcutaneous tissue and a small amount of fat left attached to the flaps (Fig 3). The triangular strip of fatty tissue remaining on the gluteal fascia is then removed with scissors (Fig 4) thereby leaving the sacrococcygeal fascia and the gluteal fascia denuded bilaterally (Fig 5). Care is exercised throughout to avoid traumatizing the skin flaps or other tissues.

4. Thorough hemostasis is accomplished by the use of plain No. 000 catgut transfexion ligatures, electrocoagulation wherever possible, and frequent copious irrigations of the wound with hot sterile saline solution.

5. Débridement of the wound is then done by carefully excising all loose tags of fat or fascia and floating out small clots and fat globules with further irrigations of hot saline solution.

6. A sufficient number (usually 8 or 10) No. 30 stainless steel through and through sutures are placed $\frac{1}{2}$ inch apart through the skin under the gluteal fascia and under the sacrococcygeal fascia (Fig 6a and 6b) to be used to exert moderate pressure in closing dead space. Several may be required close

together at the distal end of the wound to assure closure of dead space here—especially if the skin incision required extension beyond the tip of the coccyx. The lowermost deep suture may pass through the bone itself if necessary to anchor the suture firmly in the depth of the wound.

7. The skin is then accurately reapposed with No. 30 stainless steel wire vertical mattress sutures (Fig 7a and 7b).

8. After closure of the skin a thumb forceps is inserted through the upper end of the wound and any serum or blood is evacuated by exerting moderate pressure with gauze pads from below upward (Fig 8). At this point following accurate reapposition of the wound the skin and its subcutaneous tissues will remain apposed to the sacrococcygeal fascia by atmospheric pressure alone restoring the intergluteal fold (Fig 9). If however a slight tendency to sucking occurs it does not indicate that tension is present and apposition will nonetheless be accomplished when the lateral wires are secured over the gauze dressing.

9. Loosely rolled gauze dressings are then carefully placed next to the suture line and over the wound to keep the tissues apposed to the sacrococcygeal fascia. A section of sponge rubber 1 by 2 by 4 inches is incorporated into the dressing and some manual pressure is maintained throughout. The through and through wires previously placed are then twisted over the whole dressing, beginning from below upward (Fig 10a and 10b). Care must be exercised to avoid tightening the

Fig.

wires too much. The elasticity of the dressing itself maintains moderate pressure.

10. Adhesive tape is then applied to the area in such a manner as further to relieve any tendency to tension on the sutures when the patient moves about in bed postoperatively (Fig. 11).

11. All sutures are removed on the 7th postoperative day, leaving no permanent foreign body in the wound (Fig. 12).

POSTOPERATIVE CARE

Following surgery, the patients are kept at absolute bed rest on the abdomen or on either side for a period of 7 days. The penicillin in doses of 15,000 units every 3 hours intramuscularly is continued until the 8th postoperative day. The ascorbic acid is likewise continued at 100 milligrams daily by mouth. A low residue, high vitamin diet is prescribed

and evacuation of the bowel is discouraged until after the sutures are removed. These patients get along surprisingly well and in only 2 instances, when diarrhea was present, was evacuation necessary before 7 days. Fortunately, infection did not develop in either case. There was no appreciable postoperative pain and no necessity for morphine, though $1\frac{1}{2}$ grains of nembutal was prescribed for nocturnal restlessness.

After the 7th day when the sutures have been removed, an enema is given and the patient is allowed toilet and shower privileges. They are cautioned against sitting or undue exertion for a few days to avoid putting stress on the recently healed wound.

In treating the type of case described in Subgroup 3, that is, patients with recurrences who had been operated upon two or more times elsewhere and in whom there was an excessive amount of scarring and loss of skin as evidenced by the flattening of the intergluteal folds, the primary closure described was not considered feasible nor was it intended for those large postoperative scar defects.

It will be agreed that the surgical problem encountered in such cases was something more than that of the treatment of pilonidal cyst alone. Even after the most conservative treatment at operation when the scar tissue was excised, these wounds gaped widely as might be expected, so that some form of partial closure was necessary to cover the defect if the prolonged healing time and wide delicate scars associated with healing by secondary intention (27) were to be avoided.

Fig. 12.

The preoperative care and the operative procedure followed were identical with those described for the primary closure operation except that reapposition of the lateral skin flaps after excision of the scar tissue and granulation tissue pockets was not possible nor contemplated.

Accordingly the lateral skin flaps were freed and an adaptation of the horizontal mattress suture suggested by Captain Harry R. Huston M.C. U.S.N.R. Chief of Surgical Services at this hospital was used, effecting the partial closure of the defects by the expedient of securing the skin edges to the sacrococcygeal fascia. This was done by the use of 4 to 6 horizontal, figure of eight, No. 30 stainless steel wire mattress sutures that included the skin edges and the sacrococcygeal fascia.

Sections of small gauge rubber tubing were threaded on the wire sutures where they perforated the skin edges. The skin was then drawn down to the sacrococcygeal fascia with as little tension as possible and a greater or lesser gap left between the skin edges according to the amount of skin available to cover the defect. In 6 of these cases, the skin could be brought together with only a very narrow $\frac{1}{4}$ inch defect. Accurate reapposition of the skin edges was not possible with this method, nor was it sought, because of the drainage required after excision of these scar tissue cavities.

The sutures were removed on the 7th postoperative day by which time some pressure necrosis had occurred under the rubber of each suture. The skin remained attached to the fascia, however, and the center of the wounds healed by granulation tissue. These patients were kept at bed rest. Penicillin therapy 15,000 units every 3 hours, was continued for 10 to 12 days after operation. The wounds were irrigated daily with azochloramide solution 1:5000 and probed daily with a sterile cotton applicator to break down pocketing. A small dressing was then inserted and saturated with a solution containing 33 milligrams of tyrothricin per 100 cubic centimeters of sterile distilled water.

REVIEW OF CASES

Subgroup 1 In the 66 patients (Subgroup 1) who had not been previously operated upon

20 were free of gross infection at the time of admission although all patients gave a history of previous exacerbations of swelling and tenderness over the cyst area. In 46 cases infection was present upon admission. Seventeen of these 46 patients had abscesses which required preliminary incision and drainage prior to operation for radical excision. In 15 other cases of infection acute inflammation was present on admission but there was adequate drainage through the embryologic ostia. The inflammation subsided after the patient received hot sitz baths and penicillin therapy. In the remaining 14 cases infection was present as evidenced by purulent secretion expressible from the ostia but there was no surrounding inflammation or induration. In these latter cases the infection also responded to sitz baths and penicillin therapy.

Incision and drainage of the abscesses were carried out with 1 per cent procaine solution local anesthesia. An average of 4 hospital days elapsed before radical operation was performed in these cases.

As might be expected the locations of the secondary ostia and many of the scars from previous incision and drainage procedures were not conveniently located in the midline. Many of the skin incisions later made at operation for radical removal were necessarily somewhat curved or irregular in shape in order to remove both scars and sinus openings in the sections of skin removed. The narrow strip of thin skin in the very center of the intergluteal fold was always included in the excision however because it is here that the embryologic ostia are situated. In several instances the secondary ostia of these cysts were located an inch and a half or more to either side of the midline and directly lateral to embryologic ostia in the intergluteal fold. Vertical curved incisions that would circumvent both of these openings would necessarily include an excessive amount of normal skin. In such cases, the usual strip of skin was removed in the midline and small horizontal elliptical incisions were made on either side of the scarred secondary ostia. These openings were thus buttonholed the ostia with the small elliptical area of skin attached being removed with the cyst as it was dissected *en bloc*.

In 4 instances sinuses extended to the perianal area where the tracts were palpable in the fat of the ischioanal fossa. One sinus tract traversed the right ischioanal space about 2 centimeters lateral to the anal verge and opened in the perineum to the right of the urethra. There was one inverted Y shaped sinus tract, the two limbs of which flanked the anus where an ostium was present overlying each ischioanal fossa. The tracts in all cases were readily palpable.

In the differential diagnosis from fistula in ano (2 12 15) the tracts were palpable and found not to curve toward the anal canal but were traced directly to the cysts. Probes were readily introduced to trace the course of the tracts. Careful proctoscopic examinations were done and the crypts were explored with a crypt hook for possible primary ostia of fistula in ano.

At operation these sinus tracts were incised over a grooved director and traced to the cyst. They were then completely excised and the wounds closed as a continuation of the main cyst wound. The deep wire sutures traversed the depths of the wounds in the fat of the ischioanal fossae. The skin was closed in the usual manner as a continuation of the main cyst wound and the tension sutures tied over rolled gauze dressings.

In 60 of these cases the wounds were cleanly healed on the 7th postoperative day without pocketing, hematoma, or other complication. Failure in the remaining 6 cases occurred as follows: Three patients developed some pressure necrosis attendant upon the application of excessive pressure when the wires over the dressing were tightened. These patients complained of pain of a throbbing character which is indicative of this mistake. Areas of pressure necrosis $2\frac{1}{2}$ centimeters in diameter occurred on each side of the wounds where the compression sutures entered the skin. These required 15 17 and 18 days to heal. In 1 case a hematoma developed beneath the scar (2 22) making it necessary to open the overlying skin. In this case healing was complete in 30 days. In 2 cases frank abscesses beneath the skin developed which required opening of the wounds. These were probed with cotton applicators to break down pocketing irrigated

with sterile saline solution and packed with small gauze dressings containing a solution of tyrothricin, 33 milligrams per 100 cubic centimeters of sterile distilled water. The intramuscular penicillin was continued in all of these cases for 7 additional days in the first 3 and 15 days in the other 3. The tyrothricin solution was added to the dressing every 3 hours and dressings changed daily. In the abscessed patients the wounds were not allowed to gape but the skin edges were kept toward the midline by the use of large adhesive tape bridges. The dressings were applied under the bridges. The average healing time in these 66 cases was 8 7 days.

Subgroup 2 The 21 patients with recurrent pilonidal cyst comprising Subgroup 2 had been operated upon elsewhere prior to their admission and infection was present in all cases though there were no abscesses. Thirteen of them had been operated upon two or more times (In 2 instances, 3 operations) but it was impossible to determine what method or methods had been used. The common denominator in this subgroup that made them appear to be amenable to primary closure was the presence of seemingly adequate healthy skin which had not been unduly sacrificed in the previous surgical procedures.

At operation in 3 of the patients who had been operated upon once grossly appearing cystic tissue was present. All of the remaining cases were found to be recurrent because of faulty healing and the presence of chronic granulation tissue pockets (22 28) and infected scar tissue.

All of these patients were treated as in group 1 by primary closure after radical excision of scar tissue and granulation tissue pockets. In 15 of these 21 cases healing *per primam* occurred in 7 days. There were 6 failures, the longest healing time of which was 40 days and the shortest 20 days. In 1 of these 6 cases there had been severe infection upon admission considerable pocketing and scarring and 3 draining ostia 2 centimeters from the right of the midline. In this case dead space was not completely dealt with at operation or the lateral skin flaps were too long. There was pocketing under the skin when the sutures were removed and bloody purulent material

was present. The wound was partially laid open and redressed daily. A sterile dressing was placed in the wound and saturated with tyrothricin solution 33 milligrams per 100 cubic centimeters of distilled water. The tyrothricin was added to the dressing every 3 hours. Large adhesive tape bridges prevented the wound from gaping and the dressings were applied under the bridges. In 2 cases small hematomas developed which were evacuated on the 7th day when the stitches were removed. Fortunately, they occupied only a portion of the wound and the recently healed incisions overlying the hematomas were only partially separated. Here again tyrothricin was used locally in the manner described. In the remaining 3 patients although firm healing took place otherwise small unhealed areas of granulations developed where the skin was reaposed. Until these areas were thoroughly dry the wounds could not be classified as healed.

In these cases Carnoy's solution was applied and curettement of the excess granulations carried out after which a small pledget of tyrothricin soaked cotton or gauze was applied and secured by adhesive tape. Covering the wet dressings with waxed paper prevented rapid evaporation in the dressing. The first 3 failures were kept on intramuscular penicillin for 10 additional days making a total of 20 days per case. The latter 3 patients did not require additional penicillin therapy. The average healing time in this subgroup was 12.6 days.

Subgroup 3 These 13 patients admitted with recurrences of pilonidal cyst had all been operated upon elsewhere two or more times. Upon admission each of these patients was found to have persistent sinuses marked scarring and an excessive amount of skin loss over the sacrococcygeal area from previous operative procedures.

At operation the sinus tracts were found to be granulation tissue pockets due to faulty healing rather than to residual cystic tissue. In appraising these patients for further surgery primary closure was not considered feasible. The preoperative care and the operative procedure used were for the most part identical with that described for primary clo-

sure including removal of all scar tissue and the lateral triangles of fatty tissue overlying the glutea. A partial closure was then done by the use of horizontal mattress sutures through the skin and sacrococcygeal fascia. The sutures were removed on the 7th postoperative day and the wounds were irrigated with 1/5000 azochloramide solution. Daily dressings were done and frequent explorations of the wounds were made with sterile cotton applicators to prevent bridging and pocketing. Slowly healing granulations were treated with Carnoy's solution and curettement. Five of the later patients were treated locally by dressings saturated in tyrothricin solution 33 milligrams per 100 cubic centimeters of sterile distilled water. Penicillin in 15,000 unit doses, every 3 hours intramuscularly was given without interruption for an average of 18 days. The shortest period of time of healing and of penicillin therapy was 12 days (5 cases) and the longest period was 45 days (2 cases). The average healing time was 26.5 days. This is not the method of choice for the treatment of patients with pilonidal cysts not previously operated upon but it is a necessary and valuable expedient in some cases in the handling of some recurrences in which primary closure cannot be accomplished.

DISCUSSION AND CONCLUSIONS

David, Gage, Kooistra, and others have long advocated primary closure in dealing with pilonidal cyst before the advent of penicillin and tyrothricin and have presented substantiating evidence favoring the rapid healing and smaller scars attendant upon this method of treatment. Brezin pointed out that such scars are more resistant to trauma.

Tendler, Kleckner, MacFee, Theis, and Rusher and others are agreed that complete excision is essential for cure and that open pack methods of treatment result in prolonged healing and wide delicate scars. That primary skin closures prevent subcutaneous drainage and cause subcutaneous hematomas or serum collections which become infected and result in sinus formation (2, 22, 28) was not borne out by this series of cases. These complications are largely obviated in the described technique by transfixion ligature of all bleed-

ing points penicillin therapy and the use of the through-and-through wires for the compression dressing. It is well to point out, however, that in cases in which there is failure of primary healing it is most likely to be due to a hematoma which is readily apparent and palpable on the 7th postoperative day when the sutures are removed.

Magrath believes that the present appellation of pilonidal or sacrococcygeal cyst or sinus is unsatisfactory and that the present statistical method of reporting end results of operative procedures is misleading. He further states that under the present system of all-inclusiveness, one series of cases may present such extraordinary results that a surgeon may attempt the same type of operation with an entirely different type of involvement and thereby have discouraging results.

Accordingly the author has herein reported a consecutive series of cases and has attempted to lay down the criteria used in a given case in electing to use a technique of primary closure or a method of partial closure followed by tyrothricin dressings. These same criteria and techniques have been used by the writer in operating upon an additional 138 consecutive patients for pilonidal cyst since the completion of the series herein reported and have been found to be applicable in treating pilonidal disease irrespective of the extent of involvement encountered.

Fourteen months have elapsed since the beginning of this series, during which time all of these 100 patients have been followed carefully by physical examinations or through periodic questionnaires, stressing pain, soreness, drainage, swelling or any disability.

The results to date are as follows: there were 5 patients with recurrences in this series—3 of whom have been reoperated upon elsewhere and 2 who will undoubtedly require further surgery. In checking back into the operative records and case histories of these recurrences, it was found that 4 of them were in the Subgroup 3 and 1 was in the Subgroup 2. All 5 patients had been operated upon prior to the operation done by the author. In the early part of this series certain significant errors and omissions of technique and medication were made which may well account for

these failures. It was found that in 2 of these early Subgroup 3 cases in which the previous operative scars had been seemingly adequately excised and the skin undermined and secured to the fascia in the usual manner, the through-and-through sutures had been omitted and tyrothricin had not been available in the postoperative treatment. The other 2 recurrences in group 3 were, it is believed, the result of faulty surgical judgment. That is, in these 1 early cases, the lower third only, of the previous operative scars had been excised as it was in this area alone that recurrence had occurred and it seemed to be an adequate procedure at the time. The edges of the wounds were secured to the sacrococcygeal fascia after the skin was undermined in the usual manner. One patient had received local tyrothricin after operation and 1 had not. In any event, this pseudoconservatism in excising only a portion of such a recurrent cyst scar is to be condemned. The other recurrence was in Subgroup 2. The patient had been operated upon twice before and the author made an ill-advised effort to do a primary closure. This failed on the 7th postoperative day as a result of hematoma and the wound required opening and packing with arochloramide 1/5000 dressings. Here again tyrothricin had not yet been made available.

It has been observed and repeatedly recorded (21, 27) that recurrences are due occasionally to inadequate excision of the sinus but usually to infected granulation tissue lined pockets in the depth of the wound. It would seem from this fact and from a study of these recurrences, that aside from the errors of omission in failing to obliterate dead space, the continuous use of tyrothricin solution topically is an indispensable factor in combating infection in these open wounds and in thereby promoting sound healing.

Recurrence has not taken place in any of the 75 patients in whom primary closure was accomplished nor in those patients in whom partial closure with through-and-through wires and tyrothricin dressings was used, although all of these men returned to active and oftentimes, to strenuous duty in the navy and at this time to various active pursuits in civilian life.

Incisions done for drainage of pilonidal cysts preliminary to radical excision or even as a palliative measure for abscess should be made in a position giving due thought to the preservation of the skin for closure in later operation for total removal namely in the midline in the intergluteal fold whenever possible. In this manner, the artificial production of eccentrically situated ostia and sinuses can be largely circumvented and later operation simplified.

Surprisingly enough tender or painful scars have not been an outstanding sequela of this method of treatment although the fat in the intergluteal fold was almost completely excised and the wounds closed as described. In the author's experience tender postoperative scars frequently result from other factors than the lack of a fat pad over the sacrum. Tender or painful scars often occur when the skin and scar over the intergluteal fold are under tension as in the cases following elliptical incisions for block dissection and primary closure. Pain is frequently complained of in the thick, broad, adherent scars resulting from block dissection and open pack methods of treatment or in cases in which deep permanent sutures have been used. Fourteen of the 75 patients treated by primary closure reported various degrees of tightness in the operative scar upon bending over as to tie a shoe lace or discomfort upon prolonged sitting following a train ride but in no case was it an especially noteworthy complaint and these patients were highly satisfied with the results obtained. This tightness was noticeable to more or less extent depending upon the type of work done by the individual and occurred periodically for an average of 8 weeks after operation. The other 61 patients in this category reported complete freedom from any local postoperative tenderness or discomfort after initial healing had taken place. As might be expected more persistently tender scars occurred in the Subgroup 3 patients in whom the wounds had been of necessity left partially open and healed in by granulation tissue. Even here however there were individual variations in tenderness reported that were no more or less than would be expected following any secondarily healed wound in this area.

It is believed that the method of treatment herein presented largely overcomes the causes of recurrence by the use respectively of radical excisions to obviate sinus remnants and a maximum of penicillin therapy plus obliteration of dead space to prevent granulation tissue lined pockets.

In the author's opinion primary closure is the method of choice in the treatment of pilonidal cyst. The procedure is both practicable and desirable in the vast majority of cases and is adaptable even to some cases of recurrence following other procedures. It eliminates the protracted postoperative treatment and disability attendant upon open methods and circumvents the open wound and attendant infection which is such an important factor in the production of the infected granulation tissue lined sinuses of recurrences. The method results in the restoration of a normal intergluteal contour with a minimum of scar tissue that is resistant to trauma.

SUMMARY

1. A series of 100 consecutive patients operated upon for pilonidal cyst has been analyzed.
2. A technique that stresses sparing of the skin, radical excision of all cystic tissue and adjacent fat tissue, routine use of penicillin therapy and a type of primary closure that eliminates dead space was used for all patients who had not been previously operated upon (66 cases) primary healing being obtained in 90.9 per cent.
3. The same technique was used in recurrences in which the skin had not been unduly sacrificed by previous surgical procedures (21 cases) primary healing being obtained in 71 per cent.
4. Partial closure was used in treating recurrences in which the skin had been too widely sacrificed by previous operative procedures to permit primary closure (13 cases) average healing time in these was 26.5 days.

THE LATERAL ABERRANT THYROID

FRANK H LAHEY M.D., F.A.C.S. and BERNARD J FICARRA M.D. Boston Massachusetts

THE subject of the diagnosis and handling of lateral aberrant thyroid tissue is of importance for many reasons.

The existence of tumors arising in such tissue is apparently often not appreciated. They are all potentially malignant. Patients with such tumors respond well when treated by radical operation and intensive radiation. Aberrant thyroid tissue occurs in different types of tumors large and discrete as multiple gland like masses and occurring at the same time as they not infrequently do in the thyroid gland and along the internal jugular veins the tumor in this gland is wrongly considered the primary focus of malignant disease, the aberrant thyroid masses along the internal jugular veins metastases and the out come considered hopeless.

In the course of embryonic development thyroid tissue which persists outside of the thyroid gland proper is termed aberrant thyroid tissue. Aberrant thyroid tissue may be of lateral, median or ectopic origin. Lateral aberrant thyroid tissue finds its origin in the ultimobranchial bodies. At the beginning of the seventh embryonic week each ultimobranchial body united with the adjacent fourth parathyroid is set free from the pharynx. During this time growth of the thyroid brings its two lobes into contact with the ultimobranchial bodies. Each of the latter then loses its cavity and becomes incorporated into the thyroid gland. Occasionally the ultimobranchial bodies undergo conversion into thyroid tissue. This conversion is attributed to the dominating influence of a thyroid environment on a plastic, implanted tissue. To this degree the ultimobranchial bodies are lateral aberrant thyroid primordia (1) (Fig 1)

INCIDENCE

The presence of lateral aberrant thyroid tumors is not a common clinical entity. A study at this clinic revealed 30 patients with lateral aberrant thyroid tumors encountered prior to January 1939 (2). Since that date 17 addi-

tional patients have been treated up to and including June 1945. During this period 25,000 patients were treated for various types of goiter. Thus approximately 1 patient with lateral aberrant thyroid was seen for every 500 patients with goiter.

An analysis of the 30 cases seen prior to January 1939 indicates that these tumors may occur in patients at any age but usually under 40 years. They occurred five times more frequently in women than in men. Histopathologic diagnosis in all cases was papillary cystadenoma showing little differentiation into adult thyroid structure. All were considered either potentially or definitely malignant. As such, the patients were treated by radical operation followed by radiation therapy.

The 17 most recent cases studied at the clinic since January 1939 are presented in Table I.

CLINICAL PICTURE

Tumors arising in lateral aberrant thyroid tissue produce no characteristic symptoms. The presence of a swelling in the neck is noticed by the patient or found by the examining physician. Most commonly a history is given of a swelling symptomless at onset, which gradually increases in size over a period of months or years. The growth is not only gradual but may not alter its size, shape or consistency over a period of years. Occasionally, after a long period of no growth, a recent rapid increase in size may be noted and cause the patient to seek advice.

These tumors are usually multiple, producing movable gland like masses which are located along the neck in front of the sternomastoid beside the internal jugular vein (Fig 2b). At times a long chain of nodules gland like in character can be palpated from the mastoid process and at times below the clavicle along the sternomastoid muscle on one or both sides (Fig 2a). Occasionally a single deep seated tumor of the neck, firm in character, not unlike a carotid body tumor, will prove to be a single lateral aberrant thyroid (Fig 2c).

TABLE I. — SUMMARY OF CASES STUDIED SINCE JANUARY 1919

Cases, age, sex	History	Duration of symptoms	Side involved	Date of operation	Operation performed	Pathologic diagnosis	Latest follow up date
14 F	Mass left side of neck	2 1/2 yrs	Left	7-39	Left total hemithyroidectomy plus thyroid isthmus radical neck dissection	Papillary cystadenoma, metastasis to lymph nodes	11-23-43 No recurrence
15 F	Previous thyroidectomy 1931. Recurrence of mass on neck when 6 mos	7 yrs	Left	8-39	Radical left lateral aberrant thyroid tumor, left thyroid remnant, lymph nodes, and small nodes under skin scar	Recurrent papillary adenocarcinoma	6-17-44 No recurrence
16 F	Enlarged thyroid; subtotal thyroidectomy Jan 1939	5 yrs	Right	9-3-39 (4 mos after thyroidectomy)	Right radical neck dissection	Papillary cystadenoma with blood vessel invasion	1941 No recurrence
17 M	Thyroid trouble	7 yrs	Left	10-15-39	Left total hemithyroidectomy excision aberrant thyroid tumor, left radical neck dissection	Papillary cystadenoma with metastasis to one lymph node and local muscular invasion	5-17-44 No recurrence
18 F	Swelling right side of neck	7 yr	Right	4-3-40	Right total hemithyroidectomy excision aberrant thyroid, radical neck dissection	Papillary adenocarcinoma, metastasis to 3 of lymph nodes	Recurrence 3-12-44, mass up to 10-1-44; recurrent nodular goiter March 1945
19 F	Mass left side of neck	7 yr	Left	12-4	Left total hemithyroidectomy excision aberrant thyroid tumor, left radical neck dissection	Papillary adenocarcinoma with blood vessel invasion	10-21-43 No recurrence
20 F	Visible node right side of neck	7 yr	Right	6-6-41	Right total hemithyroidectomy right radical neck dissection	Papillary cystadenoma, metastasis to lymph nodes with blood vessel invasion	9-26-43 No recurrence
21 M	Aberrant thyroid found during routine examination	?	Right	6-9-43	Right total hemithyroidectomy right radical neck dissection	Papillary adenocarcinoma	7-1-44 No recurrence
22 F	Nodule left side of neck.opsy elsewhere showed papillary cystadenoma	6 yrs	Left	7-27-43	Left total hemithyroidectomy left radical neck dissection	Papillary cystadenoma with metastasis to lymph nodes	10-1-44 No recurrence
23 M	Swelling left side of neck	10-15	Left	10-43	Left total hemithyroidectomy left radical neck dissection	Papillary adenocarcinoma with blood vessel metastasis	5-17-44 No recurrence
24 F	Nodule in neck	7 yr	Right	4-16-43	Right total hemithyroidectomy excision aberrant thyroid tumor, right radical neck dissection	Papillary cystadenoma with blood vessel invasion and multiple metastases	3-17-44 No recurrence
25 F	Gravidity enlarging mass in right side of neck	10 yrs	Right	8-23-43	Right total hemithyroidectomy excision of aberrant thyroid, right radical neck dissection	Papillary cystadenoma with involvement of thyroid, metastasis to 4 of 7 lymph nodes	6-2-44 No recurrence
26 M	Neck swelling, biopsy elsewhere 1933 showed aberrant thyroid tumor. Biopsy again 1943 showed papillary adenocarcinoma	7 yr	Right and left	9-29-43	Left total hemithyroidectomy left radical neck dissection 9-29-43; right radical neck dissection 10-15-43	Papillary adenocarcinoma with metastasis to lymph nodes	10-26-44 No recurrence
27 F	Swelling right side of neck	7 yr	Right	10-6-43	Right total hemithyroidectomy radical neck dissection	Papillary adenocarcinoma with loci of carcinoma simplex	5-17-44 No recurrence
28 M	Swelling left side of neck. Biopsy 5-8-43 showed papillary adenocarcinoma	7 yr	Left	5-19-43	Left total hemithyroidectomy left radical neck dissection	Papillary adenocarcinoma, metastasis to 4 of 7 lymph nodes	Being followed at present, no report for report
29 M	Mass on left side of neck	7 yr	Left	2-28-43	Left total hemithyroidectomy left radical neck dissection	Papillary cystadenoma	Being followed at present, no report for report
30 F	Mass on neck. Biopsy elsewhere May 1943 showed papillary adenocarcinoma	1 1/2 yrs	Left	6-11-43	Left total hemithyroidectomy left radical neck dissection	Papillary adenocarcinoma	Being followed at present, no report for report

All patients received nonoperative treatment.

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of tumors originating in lateral aberrant thyroid tissue is often not made unless one recalls that any laterally located mass may be a lateral aberrant thyroid tumor. In our series before 1939 a correct diagnosis was made preoperatively in 16 per cent of the cases with a tentative diagnosis of lateral aberrant thyroid tumor. In an additional 33 per cent. As our knowledge and experience with these tumors have increased our ability to distinguish them preoperatively has likewise increased. In our second series of 17 cases the correct diagnosis was made preoperatively in 80 per cent of these patients.

Aberrant thyroid tumors must be distinguished from all the simple tumors of the neck. By dividing these tumors into median line tumors and lateral neck tumors a simple and practical classification is made available (Fig 3).

Median line tumors are for practical purposes almost all limited to the thyroid gland. They are the tumors that are limited to the descent of the thyroid. These are the undescended thyroids from their point of origin at the base of the tongue, the sublingual thyroids, the thyroglossal cysts, the pyramidal lobes and the adenomas in the isthmus. The single lateral tumors and sinuses of the neck are the branchial sinuses, branchial cysts, carotid body tumors and neurofibromas. The mul-

Fig 1

tiples tumors are the aberrant thyroids, tuberculous glands, inflammatory, nonspecific glands, the various other inflammatory types, and metastatic and nonmetastatic neoplasms in various organs of glands. In this group of multiple tumors occurs the greatest difficulty in distinguishing tumors of lateral aberrant thyroid origin. Table II will assist in the differential diagnosis of these tumors.

Fig. 2. a, This illustration shows the occurrence of a chain of gland-like bodies, often on both sides, in front of the sternomastoid muscle beside the internal jugular vein in lateral aberrant thyroid. b, Multiple gland-like bodies,

irregular in size, of lateral aberrant thyroid, occurring laterally. c, The occasional occurrence of a single, discrete, good-sized nodule, often not unlike a carotid body tumor is demonstrated.

TABLE II. — DIFFERENTIAL DIAGNOSIS OF MAIN DISEASES CONFUSED WITH TUMORS ARISING IN LATERAL ABERRANT THYROID

Disease	Age	Distribution of lesion	Character of mass	Associated findings	Course	Prognosis
Tuberculosis	Infants and children	Associated with general or local lymphadenopathy	Tender glands, chondros, matted together	Evidence of tuberculous elsewhere occasionally	Chronic	Lymph node containing Langhans' giant cells, tubercles
Lymphosarcoma	Usually over 40	Main group of cervical glands involved	Large mass matted glands not tender	Definite picture of chronic illness	Usually fatal in 1-2 yrs	Lymph node with atypical proliferating lymphoid cells in few reticulae
Hodgkin's	Mainly young adults	Local glandular enlargement, gradually becoming generalized	Marsh, discrete glands not tender	Fever (Pel-Ebstein type) eosinophilia	Chronic with fatal outcome in 1-4 yrs usually	Lymph node with Reed-Sternberg giant cells and eosinophils
Inflammatory glands	Any age	Regional glandular enlargement according to area affected	Enlarged tender glands	Evidence of primary infection; fever leukocytosis	Rapid recovery with treatment	Hypertrophy of lymph node
Metastatic carcinoma	Usually elderly males	Usually or predominantly glandular	Hard, firm glands	Evidence of cancer in thyroid, pharynx, stomach or lung	Gradually downhill and fatal	Metastatic carcinoma
Aberrant thyroid tumors	Usually under 40	Single or multiple masses occurring in chains along lateralized vessels	Movable gland-like masses	May be none	5 to 35 years of disease with adequate treatment	Papillary cystadenoma or papillary adenocarcinoma

PATHOLOGY

Macroscopic inspection of lateral aberrant thyroid tumors frequently reveals a bluish-black discoloration of the tumor tissue. This color results from blood pigment which weeps from the papilliferous elements of the tumor.

The histologic appearance of these tumors is that of a papillary cystadenomatous structure (Fig. 4). Adult thyroid elements are not visualized. This makes it difficult to identify the tissue as of thyroid origin. The macroscopic appearance of this papilliferous tissue is so characteristic and constant, however that whenever a tumor is removed from the

lateral region of the neck and is diagnosed as papillary cystadenoma, it is in all probability a lateral aberrant thyroid and is actually or potentially malignant.

Invasive tendencies are found in many of the papillary cystadenomatous nodules. Some of our cases were definitely adenocarcinoma both in cell structure and in invasive characteristics (Fig. 5). In our classification papillary cystadenoma malignant is a little more differentiated and a little less malignant than the papillary adenocarcinoma. Histologically the tumor is predominantly papillary adenocarcinoma with blood vessel invasion.

The problem often arises as to whether or not these tumors are metastatic glands with the thyroid gland as the primary site of the growth. Several of our patients have shown unilateral involvement of a thyroid lobe with a nodule of papilliferous tissue within the thyroid gland itself. In the majority of instances, however lateral aberrant thyroid nodules have occurred with an entirely normal and uninvolved thyroid gland. When the thyroid gland has been involved, equally good results have followed hemithyroidectomy including the nodule plus the removal of the lateral nodules and radiation as have followed in the cases in which no nodule was present in the thyroid. Papillary

CLASSIFICATION OF SIMPLE NECK TUMORS

Fig. 3.

Fig. 4. The typical papillary cystadenomatous structure of lateral aberrant thyroid tissue is illustrated.

cystadenomatous structures along and behind the sternomastoid muscle as well as those within the thyroid lobe itself can be explained on embryologic grounds without spread or metastasis in either direction. The lateral aberrant cell masses fuse very early in the embryo with the thyroid of median origin. Since the tumors occur anywhere laterally in the neck or in the thyroid it is probable that the papillary nodules fuse very early in the embryo with the thyroid of median origin. Since the tumors occur anywhere laterally in the neck or in the thyroid it is probable that the papillary nodules fuse very early in the embryo with the thyroid of median origin. Since the tumors occur anywhere laterally in the neck or in the thyroid it is probable that the papillary nodules fuse very early in the embryo with the thyroid of median origin.

TREATMENT

When multiple tumors of the neck are present an early biopsy to determine the nature of the lesion is important in order to undertake proper and adequate treatment, particularly when the microscopic report is papillary adenocarcinoma. A diagnosis of lateral aberrant thyroid nodules demands radical surgical

Fig. 5. Note in this papillary adenocarcinoma arising in lateral aberrant thyroid tissue all types of invasion: blood vessel invasion, perineural invasion, and lymphatic invasion.

treatment followed by intensive postoperative radiation therapy.

When a discrete nodule is found without involvement of the thyroid lobe and without other lateral aberrant thyroid nodules, complete removal may be sufficient. When several nodules are encountered dissection of the neck on that side is indicated. In the presence of invasion characteristics and the diagnosis of papillary adenocarcinoma, radical neck dissection on the side involved should be performed. This dissection includes removal of the sternomastoid muscle, internal jugular

Fig. 6. This illustration diagrammatically shows the block of tissue to be removed in patients with aberrant thyroid tissue containing papillary adenocarcinoma.

Not that this block includes the sternomastoid, the internal jugular vein, all of its tributaries entering the thyroid, all of the lymphatic nodes and all of the thyroid tissue on the side involved.

vein, all lymph nodes and total hemithyroidectomy on that side (Fig. 6)

Postoperative radiation therapy has been employed in all cases in which any criteria of malignancy were demonstrated. A total of 6000 r is applied to the tumor bed over a 22 day period. During the period of treatment serum cholesterol levels are taken. If this level rises to 300 milligrams or more, small doses of thyroid extract are administered.

FOLLOW UP STUDIES

In our series of cases prior to 1939 our follow up studies show the following: Twenty-one of our patients have been followed from 5 to 15 years. Fourteen patients have had no recurrence. During this period 3 have died of other proved causes. Three had recurrence, were reoperated upon, and are now well. Two

are living with recurrence. One patient has had repeated pathologic fractures of the right humerus and another has metastases in both lungs. One patient died of recurrent malignant disease of lateral aberrant thyroid origin. Of the other 9 patients, 6 had no recurrence after 4 years. One had a recurrence, was reoperated upon, and is now well. One patient is living with recurrence. The last patient died of metastases from carcinoma of the breast (2).

Our second group of 17 cases since 1939 encompasses a follow up period of only 6 years. In 14 of these patients recurrence was recorded, in 1 case after 4 years, followed by reappearance of lymph node metastases 1 year later. Reoperation on two different occasions revealed additional tumor. This patient is now well. Three cases are too recent to discuss.

The results of our follow up survey in the entire group confirm the pathologist's belief that tumors of lateral aberrant thyroid origin are of low malignancy. Adequate radical surgical treatment followed by radiation therapy offers a very favorable prognosis.

SUMMARY AND CONCLUSIONS

Tumors of lateral aberrant thyroid origin are discussed. These tumors arise from the ultimobranchial body as a result of departure from normal embryologic development.

Forty-seven instances of these tumors were encountered at the Labey Clinic up to July 1, 1945. During this same period 25,000 patients were treated for various types of goiter. Thus, one tumor of this type is seen in approximately every 500 goiter patients.

These tumors may occur in patients of any age but usually in those under 40 years. They are more frequent in women than in men.

Clinical diagnosis can usually be made. The lesion must be distinguished from the simple neck tumors: branchial cysts, carotid body tumors, and neurofibromas. In particular differentiation must be made from tuberculosis, lymphosarcoma, Hodgkin's disease, inflammatory glands, and metastatic carcinoma. Diagnosis is confirmed by biopsy.

The characteristic pathologic picture is a papillary cystadenomatous structure showing little if any differentiation into adult thyroid

structure. All these tumors must be considered as actually or potentially malignant.

Radical neck dissection followed by deep radiation therapy is the most satisfactory course of treatment. This lesion is of low malignancy and is radiosensitive.

The operative mortality in 47 cases was nil. Follow up studies of 30 patients prior to 1939 cover a period of 5 to 15 years. Twenty one of these patients showed no recurrence, 4 had recurrence, were reoperated upon and have remained well. Four died of other causes. One patient died of recurrent malignant disease of lateral aberrant thyroid origin.

Follow up study of our most recent 17 cases encompasses the past 6 years. One patient

had a recurrence, was reoperated upon twice and has remained well. Three cases are too recent to discuss.

In conclusion, whenever a biopsy specimen is taken of a tumor from the lateral region of the neck, and the report is papilliferous cyst adenoma or papillary adenocarcinoma, in all probability it is a lateral aberrant thyroid. Adequate surgical and radiation therapy will result in an ultimate favorable prognosis in the majority of cases.

URINARY INCONTINENCE DUE TO BILATERAL ECTOPIC URETERS

LAURENCE F. CRFENE, M.D. and EDWARD O. FERRIS, M.D.
Rochester, Minnesota

URINARY incontinence due to an ectopic ureteral orifice is not common. In 1938 Essendrach (1) reported a series of 355 cases of ureters with ectopic openings which he had collected from the literature. In most of the cases the condition was unilateral; bilateral ectopic ureters were infrequent.

The ectopic ureter is usually associated with complete duplication of the pelvis and ureter. In most instances the opening of the ureter which leads from the upper segment of the duplicated kidney is ectopic. Rarely the ureter from the lower segment is ectopic or an ectopic ureter may occur with a kidney which is not duplicated.

From the Section on Urology and the Division of Surgery, M. S. Clinic.

Fig. Excretory urogram. Duplication of the pelvis and calices of the left kidney is shown. II. Duplication of the right kidney is suggested by the small amount of medium visible in the upper pole.

In cases of bilateral ureteral ectopia the orifices of the ectopic ureters are most frequently situated in the urethra or the vestibule of the vagina. Less frequently one or both ureters enter the prostatic urethra, vas deferens, ejaculatory duct, uterus, or vagina.

The condition occurs with much greater frequency among women than among men and the outstanding symptom among women is urinary incontinence. In practically all cases the incontinence is congenital, diurnal and nocturnal and is associated with normal voidings. Among men incontinence is usually absent and the condition is discovered following investigation to determine the source of infection of the urinary tract.

The diagnosis of bilateral ectopic ureters may be exceedingly difficult and, at times, can be only inferred, as in Case 2. If the symptoms suggest ectopic ureter—the urethra, vestibule, and vagina must be carefully examined and a search made for the escape of urine from the ectopic orifice. The intravenous administration of indigocarmin is usually of little value because the function of the portion of kidney drained by the ectopic ureter is not sufficient to concentrate the dye in the urine. It may be possible to catheterize the ectopic ureters and to secure pyelograms, as in Case 1.

Excretory urography is valuable in the diagnosis of this condition. (a) In most instances bilateral complete duplication of the renal pelvis and ureters will be found. However, those segments of the kidney drained by the ectopic ureters (usually the upper) will be visualized faintly or not at all, because their function is insufficient to concentrate the contrast medium. In such instances the diagnosis of bilateral complete duplication must be inferred from the fact that the visualized pelvis (usually the lower) appear to drain only the lower portion of each kidney. Thus, if by excretory urography and retrograde pyelography a diagnosis of bilateral complete duplication of the pelvis and ureter is made and if but one ureteral orifice is situated at each extremity of the trigone, a diagnosis of bilateral ureteral ectopia can be made.

In instances in which the ectopic ureters empty into the urethra, the instillation of indigocarmin

Fig. 1 The openings of the ectopic ureters into the vestibule of the vagina.

into the bladder is of diagnostic value as in Case 2. The escape of urine, uncolored with indigo-carmin, from the urethra after the dye has been instilled into the bladder is conclusive evidence of the presence of an ectopic ureteral orifice situated in the urethra.

Because of the infrequency of this condition the following 2 cases of bilateral ureteral ectopia are reported.

REPORT OF CASES

CASE 1: A single woman, 36 years of age, stated that she had had urinary incontinence since birth and that, as long as she could recall, her underclothes had been wet. At no time had there been any diurnal, seasonal or yearly variation; at all times her perineum was constantly and monotonously wet. As a child she had been examined and treated by several physicians but to no avail. Drastic limitation of fluids and voiding every hour by the clock, during the day and night produced no change. Her parents evolved a schedule whereby the child would receive as a reward a blue paper star for each day that she remained continent and a gold star for each week, strive as she might, the unfortunate child never earned a blue star.

During puberty and adolescence the patient reconciled herself to a wet perineum. As she matured, however, she found it necessary to change her residence to another state, chiefly because her friends complained of the urinous odor. Two years before coming to the clinic she again had sought medical aid. Cystoscopic examination had been performed and she had been informed that her right kidney was infected and that the cut-off muscle was weak. A plastic procedure whereby the muscles of the urethra were tightened had been carried out but without benefit.

She stated that she used three sanitary pads during the day and three during the night. She had no other urinary symptoms. She voided easily and painlessly three or four times daily and did not have nocturia.

The only pertinent finding in physical examination was inflammation and tenderness of the skin of the vulva and

thighs; the urinous odor of these parts was evident. Routine laboratory studies, including urinalysis, yielded normal or negative results. The concentration of urea was 22 milligrams per 100 cubic centimeters of blood.

An excretory urogram (Fig. 1) revealed complete duplication of the pelvis and calices of the left kidney; the visualization of the left ureter was not sufficient to determine whether this ureter also was duplicated. The pelvis and calices of the right kidney appeared to be normal; a small amount of medium appeared to be present in the upper pole of the right kidney above the visualized pelvis and suggested the presence of duplication. The right ureter was not visualized sufficiently for accurate diagnosis.

Cystoscopy revealed the bladder to be normal; one ureteral orifice was situated at either extremity of the trigone. Bilateral retrograde pyelograms outlined only the lower pelvis of both kidneys and these appeared normal. Specimens of urine which were collected from each kidney were negative microscopically and by means of Gram's stain.

Careful examination of the urethra failed to disclose an ectopic ureteral orifice. After the intravenous administration of indigo-carmin, diligent examination of the vestibule and considerable probing of various folds finally revealed two ectopic ureteral orifices (Fig. 2). The orifice of the ureter leading from the upper segment of the right kidney was situated directly below the urethral orifice and a ureteral catheter was passed with ease. The orifice of the ureter leading from the upper segment of the left kidney was situated below and lateral to the urethral orifice. A

Fig. 3 Retrograde ureterogram. The lower portion of the ureter from the upper segment of the left kidney is dilated and tortuous. The upper segment of the right kidney and its ureter are incompletely visualized.

Fig. 4. Bilateral retrograde pyelogram. Complete bilateral duplication with bilateral ectopic ureters is shown. Visualization of the upper segment of the left kidney and its ureter is poor because the catheter could be inserted up the ureter for only a short distance.

ureteral catheter could be passed up this ureter for only a short distance and retrograde pyelogram revealed marked dilatation and tortuosity of the lower third of the ectopic left ureter (Fig. 5). A retrograde pyelogram of the upper segment of the right kidney disclosed rudimentary pelvis and ureterectasis (Fig. 4). Examination of specimen of urine from this segment revealed pyuria and bacilluria.

A diagnosis was made of bilateral, complete duplication of the pelvis, calices and ureters, with the orifices of the ureters from both upper segments situated ectopically in the vestibule. Bilateral heminephrectomy was advised and carried out.

At the time of the first operation the right kidney was exposed and it was noted that the upper segment represented approximately one-third of the total renal mass. Two sets of aberrant vessels extended to the superior pole. The upper pelvis was situated posteriorly and its ureter passed through the structures of the renal pedicle (Fig. 5). The ureter as divided in its upper third and drawn through the renal pedicle. The aberrant vessels were separated and ligated separately and the upper segment of the kidney was excised.

Convalescence was uneventful but urinary incontinence persisted. In spite of our reassurance, the patient was perturbed because it was her impression that the urinary leakage had not been reduced by half.

Two weeks after the first operation surgical exploration of the left kidney was performed. The operative findings

Fig. 5. Diagrammatic scheme illustrating the findings. Case 1.

and surgical procedures were essentially similar to those which have been described for the right kidney. Left heminephrectomy and partial ureterectomy were performed with ease.

After the second operation urinary incontinence ceased entirely. The patient was elated and stated, "It's like new life!" An excretory urogram made 3 weeks after the second operation revealed normal function in both remaining segments with no deformity of the pelvis or calices (Fig. 6). Urinalysis revealed normal findings and the concentration of urea was 30 milligrams per 100 cubic centimeters of blood.

CASE 2. A girl, 9 years of age, was brought to the clinic by her mother who stated that the child had been incontinent of urine since birth. More recently the patient had complained of burning in the region of the urethra. In all other respects the child appeared and behaved normally.

The pertinent finding on physical examination was the constant escape of small amount of urine from the external meatus. Urinalysis gave negative results. Routine studies of the blood and roentgenograms of the thorax were normal.

An excretory urogram suggested the possibility of complete duplication of the pelvis, calices and ureter of the left kidney. Although the upper segment could not be visualized, the position of the pelvis in relation to the soft tissue outline of the kidney suggested this possibility. The presence of a similar condition of the right kidney was also suggested, but details were obscured (Fig. 7).

Cystoscopic examination disclosed the bladder to be normal, with one urethral orifice situated at each extremity of the trigone. The internal vesical neck and urethral tube appeared normal. A small opening, as seen just inside the

Fig 6. Excretory urogram following bilateral heminephrectomy. Both lower segments are functioning normally. Visualization of the right kidney is incomplete.

external urethral meatus slightly to the left of the midline a catheter could be passed through this opening for only 1 centimeter. The remainder of the urethra appeared normal. Indigocarmine was instilled into the bladder and observation of the urethra did not disclose the escape of any blue-stained urine. However, an escape of clear urine from the urethra was noted at regular intervals. This finding was considered as evidence that the ureteral orifice corresponding to the upper segment of the left kidney entered the urethra. The possibility that an orifice from the upper segment of the right kidney was also situated in the urethra was considered. A recommendation of exploration of the left kidney was made. In the event that incontinence persisted after this procedure, a similar procedure on the right kidney was advised.

Exploration of the left kidney was carried out and complete duplication of the pelvis and ureter was noted. The upper half of the kidney was found to consist of a hydronephrotic sac with little parenchyma remaining. The ureter leading from the upper segment was tortuous and approximately 1 centimeter in diameter. The remainder of the kidney and the ureter from the lower segment appeared normal. Heminephrectomy, removing the upper segment, was carried out. The pathologist reported hydronephrosis, chronic pyelonephritis and hydroureter: 90 per cent of the renal substance had been destroyed.

The patient without the procedure well and convalescence was uneventful. Urinary incontinence, however, persisted. Excretory urography was repeated and the pelvis of the right kidney appeared normal but was seen to

Fig 7. Excretory urogram. The size, position, and configuration of the pelvises suggest duplication of the pelvis and calices.

occupy the lower half of the soft tissue outline of the right kidney. Considerable renal parenchyma appeared to exist above the visualized pelvis and this finding strongly suggested the possibility of duplication of the pelvis, calices and ureter of the right kidney. The remaining lower segment of the left kidney was not visualized satisfactorily but it appeared to be functioning normally.

Cystoscopy was repeated and the urethra was carefully examined, but a second ectopic ureteral orifice could not be found. Indigocarmine was again instilled into the bladder and again an escape of clear urine from the external urethral meatus was noted. This finding was considered as conclusive evidence of complete duplication of the right kidney with the ectopic opening of the ureter from the upper segment situated in the urethra.

Exploration of the right kidney was advised and carried out and complete duplication of the pelvis and ureter was found. The upper segment of the kidney was hydronephrotic and the corresponding ureter was extremely dilated. The lower segment of the kidney and its ureter appeared normal. Heminephrectomy, removing the upper segment, was carried out. The pathologist reported hydronephrosis, chronic pyelonephritis, and hydroureter: 10 per cent of the renal parenchyma was destroyed.

After the second operation the patient had perfect urinary continence. Convalescence was uneventful. An excretory urogram revealed normal configuration of the lower segments of both kidneys and both appeared to be func-

tioning normally. Ten years after the last operation the patient informed us that she had no urinary symptoms.

COMMENT

A correct diagnosis of ectopic ureter will enable the physician to achieve a brilliant cure by the proper surgical procedure—usually heminephrectomy. Female patients, miserable as a result of urinary incontinence, can be restored to perfect continence and male patients can be relieved of

intractable urinary infection by proper diagnosis and surgical treatment. If incontinence persists among female patients after unilateral heminephrectomy, bilateral ureteral ectopia is suggested and further urologic investigation of the opposite kidney, including exploration if necessary, is indicated.

STUDIES ON EXOPHTHALMOS PRODUCED BY THYROTROPIC HORMONE

III Further Study of Changes Induced in Fat by Thyrotropic Hormone (Tissue Reactions Associated With Exophthalmos)

BROWN M DOBYS MD Rochester Minnesota

IN a preceding publication (11) the reports of Paulson Aldred Brock and Smelser which described the presence of round cells in the tissues of animals given thyrotropic hormone were confirmed. Paulson (17-18) concluded that the reaction he described as Zenker's degeneration in muscle was most marked in the first few days of the administration of the hormone. I recently reported (11) that these new cellular components which appeared in tissue contained tiny droplets of fat and that the general reaction in fat depots was comparable to the reparative processes which occur in traumatized fat with fat necrosis. Fat was demonstrated by histologic techniques, in abnormal quantities not only in macrophages of connective tissue but in cardiac and skeletal muscle fibers, in liver and kidney epithelium in epithelium of the ileum and in reticuloendothelial cells throughout the body.

The nature of the reaction and the presence of fat droplets in macrophages and polymorphonuclear leucocytes of connective tissue led to the assumption that this was phagocytosis of fat and probably a form of rapid mobilization of fat. Because fat seemed to be removed from depots and appeared elsewhere in seemingly abnormal quantities, the supposition was that fat was being rapidly transported, perhaps via the blood stream. Preliminary investigation on centrifuged blood revealed lipemic plasma and a marked increase of the thickness of the buffy coat suggesting leucocytosis. In previous studies with antuitrin T the fat depots did not readily recover their depleted fat and the fat that appeared elsewhere disappeared rapidly. This prompted the question whether fat was being metabolized more rapidly than usual. Accordingly experiments were devised for the consideration of the following topics: (1) the sequence of events in the histologic changes induced in connective tissue and liver of guinea pigs

(2) a study of blood fats in such animals (3) a study of blood acetones in such animals and (4) changes that may take place in leucocytes in the circulating blood

METHODS

Inasmuch as the changes in the connective tissue of normal animals are as great as in thyroidectomized animals when thyrotropic hormone is administered normal intact animals have been used. The study was based on 14 animals receiving antuitrin T² 2 receiving purified thyrotropic factor⁴ 4 receiving specific metabolic principle and 8 normal control animals. Most interest centered about the animals receiving antuitrin T for it was this product which induced the most striking reaction in tissues (11). Twelve of the animals which received 1 cubic centimeter of antuitrin T³ were killed in 3 1/2 to 24 hours after the single administration. The remaining 2 received daily administration of antuitrin T for 2 and 3 days respectively before being killed. All animals were killed by exsanguination by means of an 18 gauge needle inserted through the thoracic wall into the heart.

Coagulation of the blood so obtained was inhibited with sodium oxalate crystals. The blood was centrifuged slowly and only sufficiently to separate the cells from the lipemic plasma. The plasma was dried, ground finely with sand and extracted three times (1 hour each) with a solvent composed of 50 per cent methyl alcohol and 50 per cent chloroform. After evaporation of the solvent, the residue was dissolved in chloroform, filtered dried and weighed.

The determination of blood acetone⁵ was done by the method of Crandall on whole blood.

One cubic centimeter of antuitrin T was reported by the manufacturer to contain 5 Junkman-Schoedler units. This unit is defined as that amount of extract which when injected daily for 3 days into guinea pigs weighing 100 and 50 grams causes recognizable hypertrophy of the epithelium and disappearance of colloid in the thyroid of out of 4 animals (3, 4).

I am indebted to Dr. Eunice Brock, of the Division of Experimental Medicine, Mayo Foundation, for her assistance in the determination of blood acetone in this experiment.

Abridgment of thesis submitted by D. Dobys to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Ph.D. in Surgery. Dr. Dobys, Fellow in Surgery, Mayo Foundation.

Fig. Phagocytosis of fat droplets by tissue macrophages and polymorphonuclear leukocytes in penturetic depot of an intact animal that had been given 5 cubic centimeters of antuitrin T daily for two days. This is the picture seen early after the beginning of the administration of antuitrin T. Some of the large macrophages suggest transformation into fibroblasts (scarlet red and hematoxylin, X750).

Determinations of fat in the plasma were made on 12 animals that received antuitrin T. Eight of these animals were also studied for blood acetone. Eight of the normal animals were studied for plasma fat and 5 of that number for blood acetone.

Attention should be drawn to the fact that some of the antuitrin T that was used had been heated at a temperature of between 95 and 99 degrees C. and pH 7 for 1 hour. This heated product caused the usual changes in fat, in connective tissue, and in organs just as the unheated product did (11).

The leucocytes from the circulating blood of these animals were studied. The cells were drawn up in a pipet from the buffy coat of the centrifuged blood. The cells were smeared on a clean slide, fixed in formalin and stained with scarlet red and hematoxylin. Such preparations were made in duplicate and triplicate to avoid misinterpretation of artifacts. This procedure served as a means of judging the presence of fat droplets in the leucocytes of the blood stream.

The liver, spleen, temporal muscle, cardiac muscle, lung, thyroid, orbital contents and fat from several depots, including periretens, axillary, cervical and testicular fat were all studied microscopically. These were fixed in 10 per cent formalin, sectioned on a freezing microtome and stained with scarlet red and hematoxylin. The pathologic changes were graded on a basis of 1 to 4 (1 being the slightest discernible change and 4 being the most striking).

RESULTS

As described previously (10) antuitrin T caused the animals to become inactive, muscularly weak and rough-coated within a few hours. The same animals which were most profoundly affected had grossly cloudy blood plasma.

The development of histologic changes. The abnormal appearance of fat in many different tissues was very evident in animals which had received a single administration only a few hours before. The liver, muscle, kidney, epithelial cells from several locations, the reticulo-endothelial cells of the lung and spleen and the polymorphonuclear leucocytes, tissue macrophages and fibroblasts of connective tissue throughout the body were sites of abnormal quantities of fat. The degree of change with regard both to the deposition of fat in abnormal quantities in various locations and to the development of the cellular reaction (with phagocytosis) in the connective tissue, became more evident as time elapsed following the injection of antuitrin T. Two animals which received antuitrin T for only 3½ hours before they were killed showed changes which could be graded only 1 to 2. Two other animals killed in 5 hours showed changes which were graded 2 to 3. By 21 and 24 hours these changes were striking, being graded 3 to 4. The tissue changes in these animals after a single injection were compared with those that were found after numerous daily administrations of antuitrin T (11). In animals treated for longer periods there were a decreasing amount of phagocytosis of fat and less fat in the liver, kidneys, muscle fibers and so forth. The new cellular elements appearing in the connective tissue remained striking but the fat droplets in such cells progressively diminished as longer periods of administration of antuitrin T were observed.

During the first few hours after the administration of antuitrin T the cellular reaction in connective tissues consisted of relatively more polymorphonuclear leucocytes and large tissue macrophages. After longer periods the polymorphonuclear leucocytes had become relatively infrequent and fibroblasts and lymphocytes had increased.

Fig. 2a.

Fig. 2b.

Fig. 2. Microscopic deposition of fat in the liver of animals receiving antuitrin T ($\times 285$). a, Three and a half hours after administration of antuitrin T. b, Five hours after. c, Twenty-four hours after.

The lymphocytes did not contain demonstrable fat droplets. Several things suggested a transformation from large mononuclear macrophages into fibroblasts. The incidence of fibroblasts seemed less very early but more common later. Cells could be found in all stages of transformation. Fibroblasts contained fat droplets just as were found in the macrophages but the quantity of fat contained had become less prominent (Fig. 1). These cellular changes were thus found to be a forerunner to the increase of connective tissue throughout the body seen particularly well in fat depots and described elsewhere (11). After 15 or more days of daily administration of antuitrin T the acute phase of the reaction had seemingly passed and in its place an increase of connective tissue was found.

The sequence of changes induced in the liver. Special attention was directed toward a sequence of changes in the liver. It was known from former experiments (11) that antuitrin T caused the appearance of fat in the liver. In 3½ hours very minute droplets of fat could be seen in the margin

Fig. 2c.

of the hepatic cells bordering the blood sinusoids. In 5 hours the fat droplets were larger and more numerous but still occupied that portion of the hepatic cells bordering the blood sinusoids. The fat was somewhat more abundant in the periportal region of each liver lobule than in other regions. Finally in 24 hours the hepatic cells were almost completely filled with fat droplets (Fig. 3). These changes were all induced by a single injection of antultrin T. This progressive accumulation of fat entering hepatic cells next to the blood sinusoids, adequately supports the hypothesis that fat is transported to the liver via the blood stream. An increased presence of fat in the periportal region of the lobule contributes additional support.

Changes induced in the thyroid epithelium. The epithelium of the thyroid gland contained many tiny fat droplets in the cytoplasm of the cell 24 hours after administration of a single large dose of antultrin T. The fat droplets were most numerous toward the base of the cell. Such droplets were not demonstrable in the thyroid cells of normal animals. Although this observation was made rather consistently the relationship of these fat droplets to the developing hyperplastic state in the cells is not understood (Fig. 3).

Changes induced in the hardenian gland. The hardenian gland, which lies within the orbit inside the periorbital, is a ceruminous gland. Its waxlike contents stain deeply with scarlet red. After the administration of antultrin T the normal waxlike contents of the cells of this gland were reduced in some animals in which considerable alteration of fat was observed elsewhere in the body. However the fact that the fat changes in this gland in some animals were not consistent with other fat changes casts some doubt on this relationship.

Results of plasma fat determinations. The presence of lipemic plasma in many of these animals which were treated with antultrin T has been mentioned. Quantitative determinations of plasma lipids after administration of antultrin T. The plasma lipids ranged from 140 milligrams to 400 milligrams per 100 cubic centimeters of plasma in the 8 normal animals. Animals killed 3½ to 5 hours after administration of a single dose of antultrin T showed no appreciable rise of plasma lipids when compared with normal animals. On the other hand after 21 to 24 hours plasma lipids were found to be as high as 1,050 milligrams per 100 cubic centimeters of plasma. Only 2 of 8 such animals were found to have plasma lipid levels which were within the range of the normal animals.

Results of blood acetone determinations. Blood acetone was calculated in terms of beta-oxybu-

tyric acid. Blood acetone of 5 of the 8 normal animals was determined. The range in these animals was 1.9 milligram to 3.3 milligrams per 100 cubic centimeters of whole blood. Seven of the eight animals which were killed in 21 to 24 hours after a single injection of antultrin T were studied for blood acetone. In this group of animals the range was 7.4 milligrams to 12.9 milligrams per 100 cubic centimeters of whole blood. Although the method of determining blood acetone may be open to some criticism, the results suggest a change in these animals that have received antultrin T.

Results in animals treated with so called purified thyrotropic factor. Two animals received 1 cubic centimeter of so called purified thyrotropic factor containing 5 Rowlands-Parkes units and were killed in twenty hours. The plasma fat was not elevated in one (380 mgm per 100 c.c. of plasma) and only very slightly elevated in another (47 mgm per 100 c.c.). Blood acetone in these animals was 0.4 milligrams and 8.3 milligrams per 100 c.c. of blood respectively. Animals receiving the specific metabolic principle showed no appreciable change in plasma fats in tissue.

Cellular changes induced in blood by thyrotropic hormone. This report is based on the following animals: 5 received antultrin T, 3 received a crude thyrotropic preparation, 3 received specific metabolic principle and 4 were normal animals. Most interest centers about the animals which received antultrin T. Not only was there an increase in the thickness of the buffy coat of the blood of animals treated with antultrin T but the polymorphonuclear cells were in great excess. A differential leucocyte count on the animals given antultrin T revealed that 82 to 94 per cent of the cells were polymorphonuclear leucocytes in 4 of the 5 animals. This is in marked contrast to the normal animals, which had 5 to 14 per cent of polymorphonuclear leucocytes in 3 of 4 animals. In the fourth animal the proportion was 50 per cent. Because of the striking increase of the thickness of the buffy coat in the blood of animals treated with antultrin T it may be assumed that the reversal of the ratio represented a polymorphonuclear leucocytosis.

A crude thyrotropic preparation caused a polymorphonuclear leucocyte response in the circulating blood similar to that produced by antultrin T. The specific metabolic principle caused a similar response in 2 of the 3 animals.

¹One Rowlands-Parkes unit is the amount which has been found to double the weight of tissue weight of the milligram (20 for 8 day rats, 200 gram female rats, 200 g will cause the thyroid double its weight of tissue weight of the milligram (20).

Fig. 3 Fat droplets in the thyroid epithelium 24 hours after administration of a single large dose of antitritin T (scarlet red and hematoxylin. $\times 300$)

Studies on Exophthalmos Produced by Thyrotropic Hormone III Further Study of Changes Induced in Fat Thyrotropic Hormone (Tissue Reactions Associated with Exophthalmos) —Brown M. Dobyns

The fat stained smear of the cells comprising the huffy coat showed fine droplets of fat in the polymorphonuclear cells. These fat droplets were very abundant and large in animals treated with antuitrin T but they were relatively small and much less frequent in the cells of the blood of normal animals or animals that had been treated with specific metabolic principle. Animals that had been treated with the crude thyrotropic preparation showed some increase of fat in polymorphonuclear leucocytes but less than the increase in animals treated with antuitrin T. A rather definite correlation was found between the presence of fat droplets in the cellular elements appearing in connective tissue and the presence of fat in the polymorphonuclear leucocytes of the circulating blood.

COMMENT AND CONCLUSIONS

In a former publication (11) there was described phagocytosis of fat in the cells which were taking part in the connective tissue reaction in animals which received pituitary thyrotropic preparations. Associated with this change were the rapid replacement of fat in fat depots by a clear gelatinous substance and the appearance of fat in many locations including the liver muscle and various epithelial and reticuloendothelial cells. In this study it has been found that after a single administration of thyrotropic hormone (antuitrin T especially) there is a rise of the plasma lipoids and of the blood acetone simultaneously associated with changes of the lipoids in many organs. These data further contribute to the belief that fat is being rapidly mobilized.

Studies of the liver reveal a progressive deposition of fat in the hepatic cells first appearing within a few hours in the edge of the hepatic cell bordering the blood sinusoids and progressively occupying more and more of the cytoplasm of the hepatic cells. Best and Campbell have shown that whole anterior pituitary extract caused fine droplets of fat to appear in the hepatic cells. This was most striking in 3 days but considerably less after 9 days. This has been confirmed with the thyrotropic preparations used in these experiments.

Anselmino and Hoffman recognized a ketogenic property in thyrotropic hormone but reported that the ketogenic action took place only if the thyroid was present. In contrast Houssay and Rietti reported such a ketogenic substance which acted in the absence of the thyroid. In the investigation described here only intact animals were used to illustrate the elevation of plasma fat and blood acetone. However all of the other tissue

reactions which were associated with the changes of plasma fat and blood acetone have been found in thyroidectomized animals just as they were found in intact animals (11).

It has been the belief of Boyd and Wilson that the polymorphonuclear leucocytes did not participate in the transportation of fat. In these experiments on the influence of thyrotropic hormone in which there was evidence of rapid transfer of fat there was also evidence that polymorphonuclear leucocytes of the blood stream contained more fat than normally. Presumably they participated in the transfer of fat. Furthermore polymorphonuclear leucocytes are found in great abundance in fat depots and they also are heavily laden with fat here as well as in the blood stream.

By chemical analysis but not by histologic technique Dible and Libman have demonstrated an increase of muscle fat of the fasting animal. I have illustrated elsewhere (11) an increase of muscle fat by histologic technique however the amount of muscle fat found in these fasting animals is very slight compared with the extreme amounts seen soon after the administration of thyrotropic hormone.

Paulson (16) has described changes in hematoxylin and eosin preparations of the hardenian glands, which he interpreted as degenerative. In the studies described here using fat staining technique it seems that the changes in the vacuolation of the cells in some animals receiving antuitrin T represent changes in the amount of lipid content. The connective tissue reaction found there is probably a part of the generalized connective tissue reaction found throughout the body.

There is a very interesting correlation between the elevation of the plasma lipoids and the appearance of lipid in the liver. In 3½ to 5 hours the appearance of lipid in the liver was comparatively slight. It was in these animals that normal plasma lipid levels were found however after 21 to 24 hours the livers were loaded with fat and in the same animals most of the plasma lipoids were found to be elevated.

In a previous publication (11) I pointed out the correlation between exophthalmos and the changes in fat with associated connective tissue reaction when thyrotropic hormone was given. MacKay and Sherrill have shown a diminution of the lipid content of the bodies of thyroidectomized rats while the body weight remains the same. Whether the fat is catabolized is uncertain. I have shown that thyroidectomy in guinea pigs and man results in an increase of the prominence of the eyes. This fact also suggests a relationship between fat metabolism and exophthalmos.

It is a well known fact that in clinical subjects following thyroidectomy the blood lipoids tend to rise and the basal metabolic rate falls. Solev (23, 24) and I (9) have both shown that with such a fall of the basal metabolic rate there is an associated increase of the prominence of the eyes in clinical subjects. That there may be similarity in these two groups of circumstances seems possible.

SUMMARY

The edema and cellular reaction in connective tissue of animals made exophthalmic with thyrotropic hormone have been studied more extensively than in former investigations.

Following the administration of thyrotropic hormone the appearance of fat in the liver skeletal and cardiac muscle epithelial cells of several locations, phagocytic cells in the lungs, spleen and lymph nodes and in polymorphonuclear leucocytes and tissue macrophages has been further studied with respect to the sequence of events taking place. The earliest cellular reaction was composed principally of polymorphonuclear leucocytes and macrophages but later lymphocytes and fibroblasts which had transformed from macrophages were most numerous. These features have developed simultaneously with the exophthalmos.

The sequence of appearance of fat in liver cells was demonstrated first as tiny fat droplets adjacent to blood sinusoids and later occupying the entire cell.

The demonstration of the appearance of tiny fat droplets in the cytoplasm of the thyroid epithelium at a time when the gland was becoming rapidly hyperplastic from the administration of thyrotropic hormone was an observation which was presumed to be related to the other phenomena observed.

The plasma fat and blood acetones became elevated simultaneously with the changes in the lipid content of many organs.

Associated with these changes was a polymorphonuclear leucocytosis. These cells were found to contain an excessive number of fat droplets in contrast to cells in the blood stream of normal animals. It is presumed that these fat laden poly-

morphonuclear leucocytes in excessive numbers in the blood stream have some relation to the similar cells which contain fat and are so abundant in fat depots and connective tissue.

These studies shed additional light on the round cell infiltration described by others in exophthalmic animals and perhaps in man. Clinical observations are briefly discussed in the light of these findings.

NOTE: Since the completion of this investigation there has appeared in the literature a study by Rundle and Peck which indicates an increase in the fat content of eye muscles in cases of exophthalmic goiter. Clin. Sci., 1944, 5: 74.

SPONTANEOUS GASTROINTESTINAL BILIARY FISTULAS

N FREDERICK HICKEN M.D. and Q B CORAY M.D. Salt Lake City Utah

CONTRARY to accepted opinions spontaneous gastrointestinal biliary fistulas are not medical curiosities. Kehr (11) encountered 100 such fistulas during the routine performance of 2 000 cholecystectomies. Puestow found that 3.5 per cent of all patients having operation on the biliary tract had these troublesome complications. The 15 cases forming the basis of this report represents an incidence of 4.2 per cent. Therefore one of every 25 patients requiring surgical therapy for disorders of the biliary tract will possess some variety of internal biliary fistulas

PATHOLOGY

Gastrointestinal biliary fistulas are always secondary to other pathological processes. It is interesting to note that gall stones proved to be the provocative agent in 90 per cent of reported cases. The close proximity of the gall bladder and choledochus to the duodenum invites the eroding calculi to escape into this portion of the alimentary tract. Six per cent of these spontaneous fistulas are produced by perforating peptic ulcers. If the ulcer is situated on the posterior surface of the duodenum they usually perforate into the choledochus, while those located on the lateral duodenal wall ulcerate through into the gall bladder. Gastric ulcers, on the other hand invariably involve the gall bladder. Cancer of the stomach, pancreas, gall bladder and common bile duct produces a degenerative necrosis of contiguous viscera so that a variety of internal biliary fistulas result. We have seen one cholecystogastric and one choledochopancreaticoduodenal fistula associated with invasive neoplasms.

An anatomic study of 272 gastrointestinal biliary fistulas reveals the incidence with which the various organs are involved. The gall bladder was involved in 88 per cent, and the common bile duct in 11 per cent. The gastrointestinal component consisted of the duodenum in 69 per cent, colon in 26 per cent and stomach in 4.4 per cent. Other fistulas were so rare as not to require notation.

The biliary dysfunctions following the formation of the gastrointestinal fistula depends largely on the nature of the causative lesion (9). Two courses are open either the fistula closes sponta-

neously or serious disturbances of the hepatobiliary system result. There is abundant evidence indicating that these fistula can and do heal voluntarily. Numerous cases have been reported wherein all biliary symptoms subsided after the gall stones had eroded into the duodenum and escaped with the feces. Two of our patients passed very large gall stones per rectum and yet subsequent operations failed to reveal any communication with the intestinal tract. In each instance the gall bladders and duodenum were so adherent to each other that they formed a homogeneous mass of scar tissue. Apparently the gall stones, by a process of ulcerative necrosis had escaped into the duodenum and the fistulous tract had been obliterated by fibrosis. We have seen cholecystoduodenal fistulas close spontaneously as soon as the provocative duodenal ulcer had become quiescent under strict management.

As a rule however the formation of these internal biliary fistulas intensifies the existing hepatic dysfunctions by producing a suppurative cholangitis, hepatitis and obstructive jaundice (3). Why do spontaneous biliary intestinal fistulas invariably produce a suppurative cholangitis while this complication seldom accompanies similar operative fistulas? In both instances regurgitated intestinal contents can be found in the biliary radicals. The explanation lies in the fact that pathological fistulas have a concomitant choledochal obstruction with the resulting stasis of bile. For example, before a migrating gall stone a perforating ulcer or a necrotizing malignant growth can produce an internal biliary fistula they provoke such an intense inflammatory swelling of contiguous tissues that a compressive occlusion of the common bile duct occurs. When the static bile becomes infected, the ensuing pancreatitis and cholangitis intensifies the choledochal obstruction.

Cholangiographic studies performed on the operating table indisputably confirm the presence of choledochal obstructions. In all of our operative cases the terminal choledochus was so completely occluded that injected diodrast could not be forced through the ampullary opening into the duodenum. Figures 2, 3 and 5 reveal that ingested barium is still incarcerated in the common bile duct 6 hours after the main body of the barium meal has passed from the duodenum into the lower ileum and colon. Tracey and McKell

From the Departments of Surgery and Roentgenology, University of Utah Medical School and Latter Day Saints Hospital.

Fig. 1. a. The prepyloric area of the stomach is occluded by an infiltrating, proliferative tumor. The barium was seen to pass from the stomach through fistula into the gall bladder but none of the barium traversed the cystic duct. Note the presence of gall stones. b. A progress film taken 6 hours later shows some of the barium in the intra-

hepatic bile ducts indicating patent cystic duct. The gall bladder still retains some barium even if the main biliary canal has progressed to the colon. Cholecystectomy thus is patent but provides inadequate drainage.

believe that the obstruction of the common bile duct with the ensuing biliary stasis constitutes the most important pathological condition encountered in these cases and it must receive primary consideration.

Fig. 2. a. Under fluoroscopic vision the barium was seen to enter the gall bladder through duodenal fistula and then flow through the cystic duct into the choledochus. Observe the pronounced dilatation of the bile ducts indicating an ampullary obstruction. The gall bladder contains gall stones. b. Same patient 6 hours later demonstrating

complete retention of the choledochal barium because of an ampullary obstruction. Note that the barium has escaped from the stomach and duodenum yet the common bile duct cannot evacuate its content through the ampulla of Vater. The dilatation of the extrahepatic and intrahepatic bile ducts signifies chronic obstructive process.

Fig. 3. a, The barium meal was seen to pass from the duodenum into the upper segment of the common bile duct by means of a choledochoduodenal fistula. No barium escaped into the gall bladder until the entire common duct was filled, and then the barium seeped along the patent cystic duct. The dilatation of the bile ducts indicates the

presence of a chronic ampullary obstruction. b, A film taken 6 hours later clearly outlines the dilated choledochus and reveals barium in the intrahepatic radicals. Note the complete ampullary obstruction which is present. This finding has been constant in all cases of biliary intestinal fistula.

SYMPTOMS

Gastrointestinal biliary fistulas produce no identifying group of symptoms but rather mimic the characterizing syndromes of the parent pathologic conditions from which they arise. For example, there are no special signs to tell whether a peptic ulcer has merely perforated into the periduodenal tissues or actually eroded into the common bile duct. Likewise an obstructive carcinoma of the stomach seldom announces that it has ulcerated into the gall bladder thereby producing a cholecystogastric fistula. The jaundice, colic, and septic reactions accompanying a choledochal stone cannot be differentiated from those arising with a choledochoduodenal fistula. So confusing is the clinical picture that the physician seldom makes a preoperative diagnosis unless the fistulas have been inadvertently discovered by the radiologist (2).

It has been pointed out that the formation of the internal biliary fistula might result in a sudden cessation of all pre-existing complaints (11). This is particularly true if the newly formed fistula effectively drains the static bile. While such fortuitous circumstances are not usual they do occur. We agree with Puestow however that the formation of the fistula usually intensifies the patient's discomfort. Nausea, vomiting, chills, fever, jaundice and colic usually compel them to seek relief.

DIAGNOSIS

The preoperative recognition of gastrointestinal biliary fistulas depends entirely on the radiologist. In reviewing the literature Borman and Rigler found that of 267 fistulas only 86 were recognized preoperatively and in each instance the diagnosis was made by the roentgenologist.

Fig. 4. This represents a reflux filling of the common bile duct associated with a duodenal ulcer. Note the irregular appearance of the duodenal cap. The biliary radicals were not dilated. A film taken one hour later failed to outline the choledochus for the barium has escaped back into the duodenum and passed into the lower intestinal tract.

Fig. 5. a, The ingested barium outlines normal stomach—a spastic pyloric ring and an irregular duodenal cap. The barium passed from the duodenum into the gall bladder thus making the diagnosis of cholecystoduodenal fistula secondary to peptic ulcer. b, After the abdomen is opened the distended gall bladder, as injected with 75 per cent diodrast. Observe the distended gall bladder and the escape of the diodrast through the fistula into the duodenum. The common bile duct is well visualized and no stones were detected. c, The cholecystoduodenal fistula was occluded by means of a rubber shoe clamp. The cholangiogram taken 30 minutes later demonstrates stasis of contrast media, for practically none of the diodrast escaped through the ampulla of Vater into the duodenum. This film confirms our contention that most internal biliary fistulae have concomitant pancreatitis which produces partial or complete obstruction of the choledochus.

In their personal series of 24 cases they made a correct radiological diagnosis in but 37 per cent. Garland and Brown were able to make a diagnosis of gastrointestinal biliary fistula in 5 cases which they studied and they assert it is the only method of making an accurate diagnosis.

The roentgenographic demonstration of ingested barium, or gas, or both in any segment of the biliary tract is presumptive evidence of a fistulous communication with the gastrointestinal tract (12). The most important single finding is the presence of barium in the biliary radicals. In only 3 other conditions does barium have access to the bile ducts. One of these is in the presence of operative internal biliary fistula and the other is where the barium regurgitates along a gaping common duct when the sphincter of Oddi is relaxed. Fluoroscopic studies usually afford an effective means of differentiation.

Cholecystogastric fistulas are recognized by the passing of the barium from the stomach

through the pathologic stoma into the gall bladder (Fig. 1a). After filling this viscus the contrast medium flows through the patent cystic duct into the common bile duct (13). Usually the sphincter of Oddi is so spastic and the pancreas so swollen that they effectively obstruct the ampulla of Vater thus preventing the barium from escaping into the duodenum. This observation is very important (Fig. 3).

Cholecystoduodenal fistulas present a different picture. The barium first fills the stomach and then passes through the pylorus into the duodenum whence it gains entrance to the gall bladder through the fistulous tract (Fig. 5). The common bile duct is not visualized unless the cystic duct is patent.

In choledochoduodenal fistulas the barium will be seen to enter the duodenum in a normal manner and then flow through the fistula into the common bile duct (Fig. 3 a). It is important to note that the barium always fills the lower

end of the choledochus first and after it becomes filled the barium ascends along the common bile duct flows through the patent cystic duct, and fills the gall bladder. Progress films invariably reveal the barium to be incarcerated in the common bile duct 6 to 12 hours after the ingested barium has passed from the duodenum into the lower intestinal tract (Fig 3 b).

Fortunately the reflux regurgitation of the barium meal along the atonic common bile duct occurs very infrequently and presents certain identifying signs (13). Fluoroscopically the barium can be seen to pass from the stomach into the duodenum, and as the duodenum becomes distended the barium slowly ascends the ampulla of Vater and completely fills the dilated common duct in a progressive manner (Fig 4). The barium however does not remain in the common duct but readily escapes through the gaping sphincter of Oddi and goes along with the main barium meal into the lower segment of the bowels. This passage of bile is in striking contrast to the choledochal retention seen in all cases of gastrointestinal biliary fistulas.

The presence of gas within the lumen of the gall bladder or the regional bile ducts furnishes indisputable x-ray evidence of a spontaneous gastrointestinal biliary fistula provided one eliminates similar gaseous shadows associated with an emphysematous cholecystitis (16) regurgitation of gas along an atonic choledochus or through an operative fistula. Rees (13) asserts that the reflux regurgitation of intestinal gases through an atonic sphincter of Oddi is so infrequent that it need not be considered. The utilization of barium meal usually provides accurate differentiation. McCorkle and Fang (10) emphasize the fact that in an emphysematous cholecystitis the gas, derived from bacterial action is usually confined within the gall bladder. In rare instances they were able to demonstrate bubbles of gas loculated within the walls of the gall bladder or confined to the percholecystic structures. This finding indicates an extension of the phlegmonous process. If the films are taken with patient in an upright position one can occasionally detect the fluids in the lower portion of the gall bladder supporting an upper stratum of gas. Duodenal intubation may permit the recovery of *Bacillus welchii* organisms.

Borman and Rigler maintain that the radiologist is so accustomed to seeing gas in the duodenum and colon that he frequently fails to consider the possibility that isolated bubbles of gas may be incarcerated in the biliary system. If the gas is confined within the common bile duct it

assumes a tubular shape which corresponds to the anatomic position of the choledochus. This gas bubble maintains a constant position which is not the case with collection of intestinal gases. Confirmatory evidence can be obtained by the administration of a barium meal.

When the diagnosis of internal biliary fistulas has been established the radiologist should make an attempt to determine the patency of the intestinal tract (2). If the migrating stones are large enough they frequently produce an acute intestinal obstruction. Scout films may furnish indirect evidence by revealing the presence of gaseous distention loculated pockets of intestinal fluids, or by localizing the offending stones. If the clinical picture is not that of complete obstruction the ingestion of a thin mixture of barium is most helpful. Such information is invaluable for the surgeon cannot hope to correct the biliary fistula while the intestinal tract is obstructed. The obstructive complication requires primary consideration.

Cholecystocolic fistulas are usually identified by a barium enema. If such enema does not outline the fistulous tract Faust and Mudgett found that the use of double contrast enema causes the insufflated air to pass through the patulous fistula so that the gas filled biliary system becomes visible.

SURGICAL MANAGEMENT

Patients having internal biliary fistulas are not good surgical risks. Dehydration, acidosis, toxemia, hypoproteinemias, all combine with the coexisting cholangitis, pancreatitis, and biliary obstructions further to depress essential functions of the liver. It requires several days of a carefully planned preoperative regimen before these patients can safely assume the added burdens of an operation. To ignore this essential preparation is to invite a high morbidity and mortality rate as indicated by reported cases.

There is no single operation which can be employed to correct all of these abnormal biliary fistulas. The remedial procedures depend on the viscera involved, the size and location of the fistulous orifices, the presence of obstructive pancreatitis, cholangitis, subhepatic abscesses and choledochal stones. Each case must be individualized.

Fistulas between the gall bladder and the gastrointestinal tract. Our plan has been to open the abdomen and make thorough palpatory examination to determine the location and extent of the provocative lesions i.e. gall stones, peptic ulcers or new growths. The gall bladder and its

fistulous tract are not molested until complete cholangiographic visualizations of the entire biliary system have been made (Fig 5 b). Visualization is quickly accomplished by inserting a No. 30 gauge needle into the fundus of the exposed gall bladder and evacuating its fluid content; then about 30 cubic centimeters of 70 per cent diodrast is introduced into the gall bladder and an x ray film is made. If the diodrast has escaped into the alimentary tract it clearly outlines the size and position of the fistula. A soft rubber-snob clamp is applied to the sinus tract and an additional 30 cubic centimeters of diodrast is introduced into the gall bladder. As the contrast medium cannot escape from the gall bladder through the fistula it will be compelled to flow along the cystic duct and fill all the biliary radicals (Fig 5 c). This affords an excellent roentgenographic pattern of the bile ducts, noting stones, strictures, and choledochal obstructions. With such information the surgeon can intelligently plan the necessary corrective operations.

When dealing with gastric malignant new growths which have extended into the gall bladder the invasive process is so extensive that resection is out of the question. The neoplastic process has usually compressed the common bile duct and the cholecystogastric fistula affords the only escape for the static bile. To molest the fistula is to invite a biliary peritonitis. We have found that the prepyloric carcinoma effectively blocks the pyloric outlet so that the increased peristalsis merely forces the gastric contents through the fistulous tract into the gall bladder, thus inciting a fulminating cholangitis. By the use of a gastrojejunostomy the gastric obstruction can be partially overcome and the reflux of the irritating stomach contents into the gall bladder is thereby reduced. One of our patients lived for 6 months after such decompressive operation, free from biliary distress, only to die of coronary occlusion.

If the cholecystogastric fistula has been caused by the migration of gall stones, it is imperative that the functional status of the common bile duct be determined before the fistula is disturbed. Should these visualizing cholangiograms demonstrate incarcerated choledochal stones, which they all too frequently do, then the common duct is opened and the offending calculi are removed. Now that the choledochus is patent the gall bladder and the fistulous tract can be safely excised, provided the patient's condition warrants this additional surgery. In many instances the removal of the common duct stones still fails completely to remove the choledochal obstruction for the associated pancreatitis effectively occludes

the ampulla of Vater. Drainage of the common duct by indwelling catheters is then required. Should the gall bladder harbor calculi they are removed and drainage of this viscus is instituted. When postoperative cholangiograms reveal the choledochus to be patent, all catheters are removed (7). It has been interesting to observe that in many instances the cholecystogastric fistula has closed spontaneously. Removal of the gall bladder can be deferred until a more opportune time.

The management of cholecystoduodenal fistulas requires special consideration. If produced by a penetrating peptic ulcer several plans can be followed. Gray and Sharpe advocate gastric resection combined with cholecystectomy and excision of the fistulous tract. Garland and Brown advise a gastric resection without molesting the gall bladder or the fistula, stating that the abnormal fistulous tract will close spontaneously. We have found that the perforating peptic ulcers are usually so large and so close to the common bile duct that resection of the ulcer presents technical difficulties. Merely to remove the stomach does not relieve the concomitant choledochal obstruction and these patients are prone to die from hepatic insufficiency. It seems that the suppurative cholangitis aggravated by the associated choledochal obstruction presents the major problem (1).

Our plan has been to individualize each case after complete cholangiographic studies on the operating table are made. In the presence of choledochal obstruction, cholangitis, and impaired hepatic function the common bile duct is opened, offending calculi are removed, and catheter drainage is employed. The ulcer and fistula are not molested. Occasionally the excavating peptic ulcer may be so large that much of the duodenal content flows into the gall bladder. Thus a fulminating cholecystitis, cholangitis, and pancreatitis are incited. While it is desirable to resect such ulcers along with the stomach the technical difficulties which it presents seem insurmountable in these ill patients. Likewise, the sequestered inflammatory tissue around the base of the ulcer precludes closure of the fistulous tract without producing duodenal obstruction. Under such circumstances, prolonged drainage by means of a choledochotomy and cholecystostomy has relieved the jaundice and permitted the ulcer to heal. Remedial gastric resections can be deferred until the patient's condition improves.

Choledochoduodenal fistulas. The vast majority of choledochal-duodenal fistulas are produced by migrating choledochal stones or from penetrating peptic ulcers. Experience dictates that the

choledochus does not evacuate all of its calculi through the fistulous tract but some stones may remain in the common bile duct. These offending calculi may be wedged in the ampulla of Vater or incarcerated in the common bile duct above the fistulous orifice. In one instance we found the common bile duct to contain 12 stones and the fistulous tract was completely blocked by a matted calculus thus accounting for the patient's intense jaundice. Before the biliary tract is disturbed operative cholangiograms are employed to determine the number and position of the offending calculi (Fig. 3). A choledochotomy with removal of the obstructive stones invariably effects a cure. The fistulous tract is not molested, unless it harbors a stone for it invariably heals by the process of fibrosis. Usually the stone laden gall bladder is removed at this time.

Penetrating peptic ulcers on the posterior wall of the duodenum present a much different problem (Fig. 5). There is such an intense inflammatory reaction that the resulting fibrosis usually produces a permanent stricture of the common bile duct. In selected cases it seems wise to remove the ulcer and stomach and to transplant the resected choledochus into the jejunum. If the patient's condition precludes these extensive operations a cholecystogastrostomy or cholecystojejunostomy may suffice. Decompression of the obstructed common bile duct can be obtained by pulling a Levine tube from the stomach through the newly formed stoma so that its tip lies within the gall bladder lumen (8). Constant suction by the Wangenstein apparatus assures complete evacuation of the static bile. This procedure has been described by us in a previous publication (8).

Cholecystocolic fistulas. Cholecystocolic fistulas are difficult to handle because of the suppurative cholangitis and hepatitis incident to fecal contamination. The fistula usually communicates with the hepatic flexure of the colon and the inflammatory reaction surrounding the anus tract is so intense that the resulting mass may produce a partial or complete colonic obstruction. One has but to review the literature to become convinced that such patients do not survive a choledochotomy all in one stage. The primary consideration is to relieve the colonic obstruction and prevent reinfection of the biliary tract. This can be accomplished by an obstructive ileostomy which effectively shunts the fecal current. The distal loop provides an excellent channel for irrigating the ascending colon with effective

germicides which help to reduce the biliary tract infections. Sulfasuxidine will likewise reduce the bacterial flora of the intestinal tract and make subsequent operations safer. Under such conservative management the inflammatory reaction about the fistulous tract soon subsides, permitting the patient to drain into the colon thus relieving the jaundiced state. When the patient's condition permits the fistula can be excised and the offending gall bladder removed. Again, may we caution that it is essential to determine whether the common bile duct is patent if not, choledochotomy must be performed. Usually the pericolic inflammation will be minimal and the size of the fistulous orifice so small that it can be closed without resection of the large bowel. No attempt should be made to establish the continuity of the intestinal tract until the fistulous stoma is completely healed. While this necessitates multiple operations a living patient is a happy reward.

OBSERVATIONS

The best treatment for gastrointestinal biliary fistulas is prevention. This can be accomplished by removing gall stones before they have time to initiate such undesirable complications. Peptic ulcers which have not responded to conscientious medical therapy should be treated by gastric resection before they have had an opportunity to erode into the biliary tract. Early diagnosis of gastric malignant new-growths combined with radical surgical treatment can minimize these invasive complications.

There are several problems which must be considered in the surgical correction of gastrointestinal biliary fistulas. First these patients must be carefully prepared to withstand the added burdens of anesthesia and surgical trauma. Second the primary surgical consideration is to remove the obstructions of the common bile duct and institute drainage thereby alleviating the biliary stasis (1). Third corrective operations such as excision of the fistula, cholecystectomy or gastric resection can usually be deferred until the patient has made a good recovery from the decompressive operation on the bile ducts.

The mortality in the 13 operative cases was 30 per cent. In each of these 4 patients who died extensive remedial procedures were carried out at the initial operation. This convinced us of the wisdom of using multiple operations particularly that of employing decompression of the common bile duct as the primary procedure. Since following this plan there were 8 patients with internal biliary fistulas which were operated upon without

SURGERY GYNECOLOGY AND OBSTETRICS

SUMMARY

- 1 Spontaneous gastrointestinal biliary tract fistulas occur in approximately 4 per cent of all patients requiring surgical therapy for disorders of the biliary tract.
- 2 Gall stones, peptic ulcers, new-growths, and surgical trauma were the etiological agents in 272 studied. This includes 15 personal cases.
- 3 A preoperative diagnosis of gastrointestinal biliary fistulas cannot be made from clinical findings alone. Careful roentgenographic diagnosis affords the only method of making an accurate preoperative diagnosis. Characteristic roentgenographic findings in the various types of internal biliary fistulas are described.
- 4 Cholangiograms, performed on the operating table, afford an excellent method of visualizing the gall bladder, fistulous tract and entire biliary tree. Cholangiograms determine the location and ramifications of the fistula and clearly depict the size of its orifices. Cholangiograms permit accurate localization and differentiation of existing choledochal obstructions, whether caused by stones, strictures, pancreatitis, carcinoma, ulcers or periductal inflammation. Such visualizing roentgenograms provide the surgeon with an accurate blueprint of problems confronting him.
- 5 The principles of corrective surgery are discussed with particular emphasis on the value of multiple stage operations.

6 Thirteen patients were operated upon of whom 4 died. A mortality of 30 per cent. One patient having a cholecystoduodenal fistula was considered inoperable because of metastatic lesion to the lungs.

RUPTURES OF MALARIAL SPLEENS UNASSOCIATED WITH EXTERNAL TRAUMA

R. RUSSELL BEST M.D. F.A.C.S. Omaha, Nebraska, and JOHN F. SCHMID M.D.
Minneapolis, Minnesota

At this time and for some time to come the frequent occurrence of splenomegaly among our soldiers returning from the many parts of the world may be considered a pathological complication of World War II. Most of these large spleens are a secondary manifestation of malaria. As our soldiers return from the various theaters and suppressive at brine therapy is no longer required additional diagnoses of malaria will be made and more cases will be important but careful examination of the left upper quadrant will reveal splenomegaly in many cases, and this finding should make alert members of the profession to the potentiality of a higher incidence of spontaneous and traumatic rupture of the spleen. The enlarged spleen assumes greater surgical significance because it is more friable and fragile and also more vulnerable to trauma with resulting rupture and hemorrhage. This is emphasized in the report of Berger in 1902 where in 123 cases of traumatic rupture of the spleen 93 showed evidence of malaria.

More than 60 cases of apparent spontaneous rupture of the malarial spleen appear in the literature prior to 1895. None of these were operated upon, the diagnoses being made at autopsy. During the last 50 years, from 1895 to 1945 47 cases have been reported. For purposes of analysis, this has been divided into two 25 year periods namely 1895 to 1920 and 1920 to 1945. During the first 25 year period, which includes some of the early years in the development of abdominal surgery, 12 cases of spontaneous rupture of the malarial spleen were listed in a report by Leighton in 1921. We have undertaken to collect all the cases from the literature between 1920 and 1945 and are able to report 35 cases.

An analysis of the 12 cases in the period between 1895 and 1920 reveals 6 deaths a general mortality of 50 per cent. Five patients were not operated upon, the diagnoses being made at autopsy a mortality of 100 per cent. Seven patients were operated upon with 1 death—a mortality of 14.2 per cent. Of the patients

operated upon 3 were splenectomized without a death, and 2 were treated by tamponment with the death of 1 several days postoperatively from anuria. In the 2 other cases only exploration with removal of blood clots was carried out as the hemorrhage from the spleen had ceased.

An analysis of the 35 cases reported between 1920 and 1945 reveals 18 deaths, a general mortality of 51.4 per cent. Fourteen patients were not operated upon, the diagnoses being made at autopsy a mortality of 100 per cent. Twenty-one patients were operated upon and there were 4 deaths a mortality of 19 per cent. Of these 21 patients operated upon 19 were subjected to splenectomy with 3 deaths, a mortality rate of 15.7 per cent. Of the 2 other cases, one was treated by tamponment with recovery and the other was explored splenic fragments only removed, and death followed. Of the 35 cases, 9 patients had been inoculated with malaria for the treatment of lues and only 1 was diagnosed and subjected to successful splenectomy the other cases were diagnosed at autopsy.

The literature contains articles and case reports on spontaneous rupture of both the normal and pathological spleen. As to spontaneous ruptures of the normal spleen we are inclined to agree with Roettig, Nussbaum, and Curtis in doubting its occurrence and believe it should be placed in question. The case reports of Sussexman (7 cases) and Zuckerman and Jacoby (21 cases) lend some arguments in favor of the normal spleen rupturing spontaneously but probably a more accurate statement would be that such spleens may not have presented discernible signs of abnormality or pathology at the time of examination because the rupture occurred at the site of abnormality, destroying all evidence of previous pathology. The term "apparently normal spleen" might be more descriptive. The factor of internal strain or trauma is probably frequently associated with so called spontaneous rupture of the normal or pathological spleen. Such internal strain associated with muscular contractions or intra-abdominal pressure changes occurring with coughing sneezing yawning vomiting effort at the stool and other body exertions must be con-

From the Department of Surgery University of Nebraska College of Medicine.

ordered. These academic factors may not be appreciated by the patient as far as their relation to his complaint of abdominal discomfort or pain is concerned. These are not unusual acts, and even the most minute questioning may not always extract the admission of their occurrence.

The onset of spontaneous rupture of the malarial spleen may be insidious and not present the picture of hemorrhage or shock in the early stages. To be alert to its possible occurrence in unsuspected situations will avoid many fatalities. Analysis and comparison of the two periods in the last 50 years reveal no improvement in the general mortality and this 50 per cent mortality is based mostly on failure of diagnosis. Certainly the technical phases of splenectomy have improved.

In the 3 cases reported in this paper a moderate degree of pain in the left upper quadrant, without a history of external trauma and without the classical signs of hemorrhage or shock, would not have resulted in early diagnoses and immediate successful surgical intervention if attending personnel had not been acquainted with the frequent occurrence of splenomegaly among military men and the possibility of spontaneous rupture of the malarial spleen.

CASE 1. J. V. Malaria was first diagnosed in this case about January, 1945, in New Guinea. He was treated with quinine, atabrine and plasmoquin and during the following months had two recurrent attacks. He returned to the U. S. States on rotation in November, 1944, and atabrine was discontinued. In January and March, 1945, he had recurrent attacks and was treated with atabrine. During the second attack in March, he went to sick call in the morning and fainted while waiting. He was admitted to the hospital, *Plasmodium vivax* was demonstrated and atabrine was started immediately. He complained of slight upper abdominal distress. During the afternoon of this day he began complaining of more abdominal distress and weakness. About 30 that evening, he collapsed while making an effort to the bathroom. He was again seen by a medical officer. There was increased upper abdominal pain and pain in the region of the left shoulder. The abdomen was distended and there was tenderness over left upper quadrant and lumbar areas. There was no fluid wave or shifting dullness. The blood pressure was 65/30, pulse 64, hemoglobin 9.5 grams. With plasma and blood transfusion, his general condition improved. Intramuscular atabrine therapy was started. The patient was operated upon under nitrous oxide gas-ether-oxygen anesthesia and the spleen was removed. The peritoneal cavity contained free blood and clots. There were three definite points of rupture on the convex margins of the spleen. He made an uneventful recovery.

Pathology: The spleen weighed 335 grams and was very friable. Serial sections showed small infarct. Microscopic examination showed focal necrosis of malpighian bodies. Malarial parasites were seen.

CASE 2. H. C. This patient developed malaria in the South Pacific in September, 1944. He continued on suppressive atabrine therapy until the day of admission to the hospital months later. For week prior to entering the

hospital, he had been constipated and had had no bowel movement. On this morning, he went to the toilet, strained severely and at this time noticed a sudden, rather severe pain just to the left of the epigastrium and under the left costal margin. Following this, he felt nauseated and retched several times. He felt little weak and returned to his bed to rest a little longer. In the afternoon, because of continued abdominal pain and marked distress in the region of the left shoulder, he entered the hospital.

Examination revealed a soldier in apparent distress. His abdomen was quite rigid, more so on the left, and there was marked tenderness in the epigastrium and beneath the left costal arch. The blood pressure was 100/54, hemoglobin 1 grams with 3.0, 0,000 red blood cells per cubic centimeter. Platelets were 140,000. Prothrombin time was 8 seconds for this patient and 7.5 for the control. In view of his history and the clinical findings, immediate operation was advised. Intramuscular atabrine therapy was started at once. On arriving in the operating room, his blood pressure dropped to 58/30 as he was moved from the cart to the operating table. Plasma was started immediately but he had been typed so blood was available in a few minutes and transfusion was given. The blood pressure returned to 90/60 and under nitrous oxide gas-ether-oxygen anesthesia, the spleen was removed through a transverse abdominal incision. When the peritoneal cavity was opened, a large amount of fresh and clotted blood was encountered. The spleen was palpated but no break in the capsule was found. Adhesions were very firm to the diaphragm. The splenic pedicle was gently exposed and a small vein, about 1 millimeter in diameter, was seen to be bleeding rather freely as a clot was lifted from this area. With the application of a clamp to the vein, bleeding stopped. No break in the splenic capsule could be ascertained before removal of the enlarged spleen. There were several areas of subcapsular hemorrhage. He made an uneventful recovery but a transfusion was given on the third postoperative day because of 9 grams hemoglobin and a 3 per cent hematocrit.

Pathology: The spleen weighed 370 grams. On microscopic section, the germinal centers of the hyperplastic malpighian bodies were partially necrotic. Occasional ring forms and schizonts of *Plasmodium vivax* were present in the erythrocytes.

CASE 3. C. B. This patient had his first attack of malaria in North Africa and remained free from recurrence as long as he continued to follow the suppressive atabrine therapy religiously. On several occasions, he omitted taking his daily tablet and within a matter of weeks he would have recurrent chills and fever. On one occasion when he had discontinued his therapy for some days, he had the opportunity and desire to eat an unusually heavy meal. That night he awakened about 1:00 a.m., felt nauseated, and induced vomiting by inserting a finger in his throat. While vomiting, he felt a severe, stabbing pain under the left costal margin and felt very weak on returning to his cot. He was unable to get much rest because of pain and the following morning reported for sick call. Because of pain and tenderness under the left costal arch, he was sent into the hospital. On examination, an enlarged and very tender spleen was palpated. There was tenderness in the epigastrium and left lumbar regions. Pulse was 94, systolic blood pressure 98, diastolic 64, hemoglobin 15 grams with 4,300,000 red blood cells. He had an attack of chills and fever soon after reaching his bed, and by this time positive malarial smear was reported. The patient remained very uncomfortable and stated that he felt something was pushing out his ribs. During the next 6 hours, his pulse increased to 120, the blood pressure dropped to 90/60. With the history of malaria and the large, very tender spleen with muscle rigidity more marked over

left rectus and lumbar regions without urological symptoms or positive urological findings by x-ray the diagnosis of a ruptured spleen was made and operation advised. Through a transverse incision the peritoneal cavity was opened. There was no evidence of free blood. The spleen was greatly enlarged and further exposure revealed a massive subcapsular hematoma. While manipulating the spleen for removal, the capsule ruptured and a large hematoma was partially released. At this moment the patient's general condition became rather poor; pulse became weak and blood pressure dropped. Plasma was started and he responded immediately. This was followed by whole blood, a donor having been selected before operation. No anesthetic was used. The pathologist reported a malarial spleen with parasites present.

Three types of rupture have been demonstrated in these cases—namely rupture of capsule with free bleeding; subcapsular rupture with massive hematoma development beneath the capsule and rupture of a vein in the splenic pedicle associated with several small subcapsular hematomas.

An analysis of these cases reveals that the patients began having rather sudden mild to moderately severe pain in the left upper quadrant with radiation varying to the epigastrium, left lower quadrant and lumbar regions. The onset may occur while the patient is apparently inactive or while making some slight exertion. Nausea or vomiting may be associated with this distress and there may be some feeling of weakness and a desire to rest and remain quiet. Two of these patients had a positive Kehr's sign with pain in the left shoulder to which one should attach great significance in a suspicious or known case of splenomegaly as it usually means leakage of blood beneath the left side of the diaphragm. Balance's sign with percussion dullness in the left upper quadrant is not so important as to indicate blood in this area because of the already enlarged spleen. However it is significant as to the presence of a large spleen and the possibility of spontaneous rupture. Tenderness and rigidity on the left side including epigastric and lumbar areas are most significant if there is a history of malaria. A history of overseas service with prolonged suppressive atabrine therapy should alert one to malaria even in the face of no history of chills and fever. Pulse, blood pressure and blood picture changes may not be present in these cases in the early period. With some of the typical picture of hemorrhage and shock in addition to a suspicion or knowledge of splenomegaly one can readily establish the diagnosis.

In the differential diagnosis, perforated or penetrating peptic ulcer ruptured gall bladder mesenteric thrombosis, volvulus, renal colic, diaphragmatic pleurisy pancreatitis and coronary

occlusion must be considered, but if the history can relate the heretofore mentioned facts regarding the possibility of malaria and splenomegaly, a prompt and probably correct diagnosis will be made immediately or after a few hours observation.

It is very advantageous in these cases that proper medical management be instituted immediately on diagnosis and, if possible, before the patient is operated upon. A chill occurring between the period of diagnosis and splenectomy may not only prove hazardous for the patient but embarrassing to the surgeon and the anesthetist. Anesthesia and surgery are both factors which tend to precipitate recrudescence of malaria. Strong in his text, cites Manson Baker reporting a reduction of red blood corpuscles by as much as one million per cubic millimeter with a single chill.

Quinine dihydrochloride by intravenous route has long been advocated for malarial crises because of the rapidity with which a high blood level is obtained. However Hudson has emphasized the fact that the peak level of quinine used intravenously is over within 30 minutes and that by large intramuscular doses of atabrine a quick more sustained therapeutic level is attained. An effective plasma concentration is reached within 15 minutes and maintained 6 hours by a 0.4 gram intramuscular dose. Consistent with this reasoning and in an attempt to avoid the depression associated with large, rapid doses of quinine atabrine dihydrochloride was selected for treatment in these cases. Upon diagnosis and before the patient was operated upon a 0.4 gram dose of atabrine dihydrochloride was given intramuscularly half of the dose into each buttock. Thereafter 0.2 gram were given intramuscularly every 8 hours until the patient could tolerate oral medication. Usually this occurs within 24 to 72 hours postoperatively and atabrine 0.1 gram is given three times daily for about 6 days or until 2.8 grams have been administered. Sodium bicarbonate was employed in 1 gram doses three times daily with the oral atabrine. Each patient was continued on suppressive atabrine therapy (0.1 gram daily) for a 30 day period following the emergency. In these cases, one or more transfusions of whole blood supplemented each operation. The rationale of this treatment is to prevent the occurrence of an inopportune chill before during or immediately following the operation to prevent or overcome the cachexia which occurs with the acute malarial attack and to prevent recrudescence of clinical malaria during the convalescent period.

The treatment is splenectomy and if tamponment and suture have no place in the fracture of the normal spleen, they certainly have no place in the management of the more friable malarial spleen.

SUMMARY

1 Splenomegaly is common among military personnel who have served overseas.

2 Apparent spontaneous rupture and traumatic rupture of the spleen will be more frequent because the enlarged spleen is more friable and more vulnerable to external trauma and internal strains.

3 The apparent spontaneous rupture of the spleen is probably associated with some form of unappreciated or unrecognized external trauma or internal strain.

4. A series of 12 and a series of 35 cases of spontaneous rupture of the spleen are reported.

5 Three additional cases with recovery following splenectomy are reported.

6. There has not been improvement in the general mortality rate for spontaneous rupture of the malarial spleen in the last 50 years. The figure remains at about 50 per cent and is based on failure of diagnosis or delayed diagnosis.

7 Splenectomy is indicated.

8 It is important to institute antimalarial therapy as soon as diagnosis is made and before operation if diagnosis has been made.

9 Atabrine is the drug of choice.

EXPERIMENTAL SURGICAL PULMONARY COLLAPSE

DAVID A. WILSON M.D., Greenville South Carolina, and HORACE BAKER, M.D.
Durham North Carolina

VARIOUS extrapleural stripping procedures have been introduced into the field of thoracic surgery since the initial report by Tuffier (95) in 1891. These procedures have all arisen as a result of a demand for a simplified operation which can be used in poor risk or complicated cases requiring collapse therapy. From a theoretical standpoint the operative procedure is sound in that relaxation in all directions can be secured by an extrapleural freeing of the lung just as in an intrapleural pneumothorax. Many present day surgeons combine an extrapleural dissection with thoracoplasty for the same reason and find no objection to a combination of operations (Semb).

Extrapleural pneumolysis as a primary procedure, however has met a great deal of criticism, more so in this country than abroad. The criticism appears to be based not so much on the operative approach to the problem as upon the frequency of complications which arise and because these complications are so difficult to manage. Extrapleural pneumolysis, unlike intrapleural pneumolysis, leads to the creation of a nonserous lined space with a distinctively different physiological reaction. The same end-results may be obtained in so far as collapse of the lung is concerned. Churchill (16-17) has stressed the fact that extrapleural pneumolysis, in contrast to intrapleural pneumothorax is an irreversible procedure and should be considered as such. In an attempt to make a reversible procedure out of an irreversible one, air was utilized to maintain the space and met with disrepute. The threat of infection was forever present and sooner or later the air had to be replaced by oil or the space had to be obliterated by a thoracoplasty (Dolley, Jones, and Skillen 18-19). Fundamentally then it can be said that the operation of extrapleural pneumolysis is sound but the methods of maintaining the space are unsatisfactory. With this consideration in mind experimental studies were begun in the Fall of 1943 to discover a material which could be used to fill an extrapleural pocket which would be nonirritating to the tissues, and which would permit the body fluids to organize forming a permanent fibrous pack. An ideal

material was found in methyl methacrylate commonly known by its trade name of lucite.

HISTORICAL

Extrapleural pneumolysis is not a new operation. The procedure was first described by Tuffier (95) in 1891. The first recorded operation in this country was performed by J. B. Murphy in 1898. In 1910 Tuffier (99) reported 3 cases and noted the need for some material to maintain the collapse. In 1914 (97) he reported 11 cases in which the cavity was filled with the patient's own fat. In this series there were 4 deaths and only 1 cure. Bull also used fat in 9 cases with healing in 5. Morrison Davies reported 4 cases improved by filling with fat. Fat was soon discarded as a filling material because it was too difficult to obtain in an emaciated person because it was too soft and because liquefaction occurred.

In 1913 Baer (?) recommended extrapleural pneumolysis because of its simplicity and because it avoided extensive skeletal operations. He employed a paraffin mixture, consisting of 75 cubic centimeters of paraffin with a melting point of 58 degrees centigrade and 25 cubic centimeters of paraffin with a melting point of 50 degrees centigrade plus 1 gram of bismuth carbonate and .05 gram of vioform. The paraffin mixture was sterilized by vapor sterilization on 2 successive days for 1 hour and warmed before using. The mixture hardened at body temperature and met the chemical requirements better than fat. Sauerbruch (79-80) was first to carry out a large series of cases with this material and Nissen (65-66-67-68) and his co-workers, pointed out indications and shortcomings of the paraffin pack. Complete obliteration of the pleural cavity is of prime necessity since the obliterating material causes a marked foreign body reaction which combined with gravity may result in a tear of the parietal pleura with penetration of the free pleural cavity. The same process leads to a necrosis of the lung overlying adjacent thin walled cavities. This most dreaded complication results in a severe infection and demands immediate removal of the pack. The pressure necrosis of the lung overlying thin walled cavities is attributed to the interruption of venous and arterial communications from the thoracic wall through the pleural adhesions.

From the Department of Surgery, Duke University School of Medicine and Duke Hospital.

Fig 7 Roentgenogram of chest and uterine atrophy of rat No. 7 showing collapse of right lower and middle lobes 9 weeks

after insertion of methyl methacrylate mold into the pleural cavity

the blood supply from the lung to this area having already been interrupted by the cavitation. Too little attention has been given to the foreign body reaction created by paraffin. It is our opinion that this is of greater importance than the interference with the blood supply.

Baer (7,8,9) recommended performing the operation through an anterior incision. Nissen preferred a posterior approach and limited the mass to 500 or 600 cubic centimeters. Head has recently advocated the paraffin pack for closure of large apical cavities which are prone to retreat against the spine or mediastinum and remain patent despite extensive thoracoplasty procedures, including removal of the transverse processes and costal cartilages. He observed a higher percentage of favorable results than when thoracoplasty was performed as an initial operation. He also advocated the initial paraffin pack as a less dangerous procedure with a good chance of cavity closure. Furthermore he felt that thoracoplasty performed after initial paraffin packing was more apt to be effective and attended by less complications because of the reduction in size of the cavity and stabilization of the mediastinum. He reported 31 patients selected as being suitable for initial paraffin filling. Of these 31, 24 had conversion of sputum from positive to negative. Three were improved, 2 were worse and 2 died. Sixteen had large apical cavities, 6 of which were converted by packing alone and 7 others by packing and thoracoplasty. In 4 cases the paraffin perforated the lung and had to be removed.

Schlange, Sauerbruch (79,80) Casper and Matson (54,55) advocated compression with an extrapleural pack of plain gauze. Matson (54) in 1938 in a preliminary report advocated an extrapleural gauze pack in apical and subapical soft walled cavities of recent origin, preferably less than 4 to 5 centimeters in size with a patent bronchus. In general he employed the gauze pack in those cases in which extrapleural pneumothorax would at that time have been the logical procedure to utilize, that is, in those patients with tuberculous cavities or areas of infiltration in either one or both upper lung fields. The collapse was selective in character and he felt that the postoperative management was relatively simpler than extrapleural pneumothorax. Of 81 patients reported, 54 had conversion of the sputum, 15 were considered clinically well after the pack was removed. There were 4 deaths none directly attributed to the operation. Infection occurred with the formation of a purulent exudate in 18 cases and in 16 removal of the pack was necessary. Removal of the pack was followed by thoracoplasty in a large percentage of these cases.

Shivers, Archibald (4,5) Goffaerts and De Winter (34) Sebrechts, Alexander (2, 3) and Churchill (16, 17) have advocated filling an extrapleural cavity with pectoral muscle detached from the chest wall and humerus. The sternal and coracoid attachments were preserved with the main blood supply in order to diminish atrophy of the muscle. Archibald (4,5) Butler, Skinner, Douglass, and Merkel combined muscle packing

Fig. 3. Roentgenogram of chest and autopsy of rat No. 7 six months after insertion of $\frac{1}{4}$ inch methyl methacrylate balls into the pleural cavity. The balls are still free in the pleural cavity

with thoracoplasty removing the anterior portions of the second third and fourth ribs while Goffaerts and DeWinther performed an extrapleural pneumolysis through an anterior approach resecting a portion of the third rib and pulling the pectoral muscle through the first intercostal space. Alexander (3) and Lilienthal (51, 52) advised a supraperiosteal and subcostal filling of muscle performed through a curved

anterior incision in preference to an extrapleural packing. In this modification the periosteum of the first three or four ribs is stripped free and is displaced medially by the pack. Re-expansion is prevented by regeneration of the ribs in this location deep in the thorax. The advantages of this modification over extrapleural stripping is that there is less danger of tearing the pleura and the extent of the pulmonary collapse is readily

Fig. 4. Photomicrographs of the pleura and lung in contact with methyl methacrylate: a, left, weeks; b, 6 months. $\times 195$.

controlled by the amount of periosteal stripping and is not limited by the presence of tough extrapleural adhesions. The indications for supra-periosteal and subcostal packing are extremely limited. The limitations are much narrower than those of extrapleural pneumothorax and more closely approach anterior thoracoplasty in operative technique. With present day perfection of technique in performing thoracoplasty it is doubtful if any case of pulmonary tuberculosis is more suitable for this procedure.

Gwender, Jensen (46) Müller and Oughterson and Harvey (70) used an inflated rubber balloon inserted in the extrapleural space for the treatment of tuberculous pulmonary cavities. Haight, Harvey and Oughterson (40) used a similar balloon placed suprapariosteally for the treatment of nontuberculous cavities. This temporary collapse was maintained until the patient's condition permitted a thoracoplasty or an unroofing operation. Infection occurred in the majority of patients, and the postoperative management was complicated.

The maintenance of an extrapleural collapse by means of air refills is of relatively recent inception. Mayer in 1913 first demonstrated that it was possible to do a complete extrapleural stripping of the lung including the pleura over the diaphragm. Jensen (47,48) and Rieckenberg reported a series of successful cases. In 1933 Romanis and Riviere (74) reported an extensive extrapleural stripping with re-expansion because of delay in instituting the refills. In 1933 Jachia and Sebestyén advocated extrapleural pneumothorax in conjunction with an unsuccessful intrapleural pneumothorax. Serious attention was not given to extrapleural pneumothorax until the publications

of Graf (35,36) Schmidt (82,83) Moraldi, Nussen (65,66,67,68) Michelsson and Zorn between 1933 and 1938. In 1936 Graf (35,36) reported 107 cases with favorable results. In 1937 Schmidt (83) reported 155 cases and increased the number to 544 by May of 1939 (Adelberger, Thoms, Bellingier, Gaubatz, and Sauer). Large series of cases did not appear in the American literature until 1938 (Overholt and Tubbs, Belsey). At first received with considerable enthusiasm it immediately became apparent that air was not an ideal material for the maintenance of an extrapleural pocket. Unlike the serous lined intrapleural cavity the extrapleural space was maintained with difficulty, complications were frequent and re-expansion failed to occur following discontinuance of the refills. The space then had to be obliterated by thoracoplasty or converted to an oleothorax with its ever attendant danger. Dolley Jones and Skillen (18,19) in a comprehensive survey reviewed the results of over 277 cases gathered from 27 clinics where extrapleural pneumothorax had been in use for more than 2 years. The results varied with the character of the patients selected for operation. Conversion of the sputum occurred in only approximately 53 per cent of the patients and 11 per cent were dead. Early conversion of the pocket by means of oleothorax was advised in order to control and maintain the collapse, to reduce the expense of refills, and to minimize the chances of infection. On the whole the report was not favorable.

EXPERIMENTAL STUDIES

In the search for an ideal substance to be used as a packing material for an extrapleural space certain fundamental considerations were appar-

Fig. 5. Roentgenograms of chest of dogs showing a, collapse of apex, b, collapse of middle portion, and c,

collapse of lower lobe of the right lung by means of methyl methacrylate balls inserted into an extrapleural pocket.

ent. Since the material chosen was to be left in the extrapleural pocket permanently thus establishing an irreversible collapse comparable to thoracoplasty (1) the material should be non-irritating to the tissues, both in the immediate postoperative period and in later stages (2) it should be noncarcinogenic and nonantigenic (3) the material should be of light weight so that a large quantity could be introduced without danger of penetrating the pleural cavity and lung (4) it should be insoluble and not subject to chemical change in the tissues (5) it should offer little if any resistance to x rays (6) it should be capable of being premolded in such a shape that varying sized cavities could be filled through a relatively small incision.

The various metals and nonmetals which came under investigation included aluminum, tantalum, vitallium, preserved cartilage, stainless steel, celluloid and methyl methacrylate. The metals, especially tantalum and vitallium, were considered ideal in so far as the tissue reaction was concerned but were discarded because of the weight and expense. Celluloid and methyl methacrylate are both relatively inexpensive and light weight. Both have been used in orthopedic surgery and in neurosurgery to repair bone defects but nothing to our knowledge has been reported concerning their use in thoracic surgery. Celluloid was first used by Fraenkel in 1890 for the repair of cranial defects and gained wide popularity for this purpose in the early part of the century. Experimentally the tissue reaction has been shown to be slight. Immediately after the operation a serosanguineous exudate formed

about the celluloid which frequently required aspiration. Six days after implantation the celluloid was surrounded by granulation tissue containing newly formed vessels and polymorphonuclear leucocytes. After 4 weeks laminated connective tissue still infiltrated with inflammatory cells was present. Nev reported 300 implants with but 5 infections. If infection did not occur encapsulation took place. Several operators have found little reaction after several years. Funke (29, 30) however found that the celluloid lost its elasticity, became brittle and crumpled, and chemical analysis showed that camphor was lost from the implant. It has therefore been discarded.

Methyl methacrylate is an acrylic resin manufactured from acetone, hydrogen cyanide and methanol in the presence of sulfuric acid. The end product is a clear liquid called methyl methacrylate monomer. Under exacting chemical and physical conditions polymerization takes place giving rise to the clear solid form which is marketed commercially under the trade names of lucite, crystallite, plexiglass, and vitallite. In the finished form methyl methacrylate exhibits a tensile strength of 6,000 to 9,000 pounds per square inch. It is thermoplastic and softens when heated to temperatures above 220 degrees Fahrenheit (105 degrees centigrade). It absorbs only a small amount of water without changing its chemical composition. Methyl methacrylate is soluble in esters, ketones, ethylene dichloride and chloroform; it is not affected by weak acids or alkalis.

Methyl methacrylate was first used in dental prostheses and found to be nonirritating when in contact with the mucous membranes over a long

Fig. 6. a. Lung of dog No. 5 removed at autopsy 5 months after extrapleural packing with methyl methacrylate balls.

period of time. Kleinschmidt in January 1940 was the first to report its use in experimental animals, to repair skull defects. In the first few days the plate was found to be surrounded by a small amount of serum which rapidly organized, forming a definite capsule of hyaline connective tissue. There was little inflammatory reaction and no foreign body response even after the presence of infection. Kahn believed the material could be safely used at the time of a primary repair of a perforating wound of the skull, and even in the face of infection the plate need not be removed.

With these studies in mind, methyl methacrylate appeared to fulfill the qualifications of a satisfactory filling material to maintain an extrapleural collapse of the lung. Animal experiments were begun in November 1944 to determine the reaction of methyl methacrylate implanted into the extrapleural space and into the pleural cavity. Operation was performed on 30 adult rats and 10 dogs. In some of the rats collapse of the individual lobes was secured by implanting a mold of the lobe to be collapsed directly into the pleural cavity (Figs. 1 and 2). In other rats a portion or the entire pleural cavity was filled with $\frac{1}{4}$ inch balls introduced through a small opening in the chest wall (Fig. 3). The operation was performed with positive pressure anesthesia under sterile precautions. In the postoperative period frequent x-ray films of the lungs were taken. The rats were killed at intervals of from 10 days to 8 months and postmortem examinations were made. A little effusion was demonstrated following the introduction of the methyl methacrylate into the pleural cavity but the animals tolerated the material well and except for some shortness of breath in the first few days, activity was normal.

Histological studies of the pleura and underlying lung in contact with the implants showed (1) varying degrees of atelectasis of the lung (Fig. 4). In 16 rats atelectasis was present without inflammation. In 4 rats a pneumonic process was present with multiple small abscesses confined to the atelectatic portion of the lung. Empyema was associated with 2 of these cases. (2) A minimum of pleural reaction characterized in the first few days by the formation of a small amount of clear fluid around the implants accompanied by a swelling of the mesothelium and

b

c

Fig. 6. b. Photomicrograph of section through collapsed area of lung compared with normal lung. X85.

proliferation of the connective tissue in the submesothelial region. The mesothelial lining of the pleura remained intact in most instances and a few large eosinophilic staining cells resembling mast cells were observed in the submesothelial region. There was no round cell infiltration or giant cell formation (Fig 4).

In 18 of the rats the fluid around the implants became organized into a thin film of hyaline connective tissue infiltrated at the periphery with newly formed capillaries and a few chronic inflammatory cells. In 10 rats the implants were still free in the pleural cavity at the time of autopsy (Fig 4). Two rats died on the fourth and twelfth postoperative days and autopsy revealed empyema with the formation of abscesses and granulation tissue around the lucite balls and in the underlying lung tissue.

An extrapleural collapse was performed on 10 healthy dogs which were then followed clinically and roentgenographically for 6 to 8 months (Fig 5). Approach to the extrapleural space was easily secured between the ribs but because of the tissue paper character of the parietal pleura its close attachment to the periosteum of the ribs, and its extension high into the neck, classical extrapleural stripping in the dog was found to be extremely difficult. Dissection of the inner periosteum from the rib was frequently necessary. The space when developed, was filled with solid $\frac{3}{4}$ inch methyl methacrylate balls. In 8 of the 10 dogs a serosanguineous exudate appeared within 48 to 72 hours postoperatively resulting in moderate swelling of the operative site and requiring aspiration in 1 dog. Infection in the operative incision occurred in 1 dog requiring open drainage. Healing eventually occurred however with penicillin therapy and without removal of the lucite balls. There were no deaths in the series of 10 dogs and no evidence of any systemic reaction after the immediate postoperative period.

Autopsies revealed a localized atelectasis of the lung adjacent to the extrapleural pack (Fig 6). There was a moderate thickening of the mesothelial layer and microscopically some proliferation of the submesothelial connective tissue of the visceral pleura similar to that observed in the rats. Adhesions between the visceral and parietal pleura were absent in 7 of the dogs. In 3 fine string like adhesions were present. The methyl methacrylate balls in the extrapleural space were fixed in a dense mass of hyaline connective tissue (Fig 7).

EVALUATION

Methyl methacrylate introduced into the pleural cavity and extrapleural space of experi-

Fig 7 Photomicrograph of connective tissue surrounding the methyl methacrylate balls inserted into the extrapleural space. $\times 127$

mental animals is well tolerated. It is light weight, readily available, inexpensive and non irritating. Its reaction is characterized by the production of a thin capsule of hyaline connective tissue.

The adaptation of methyl methacrylate to clinical surgery is opening new horizons. At the present time it is being used to repair cranial defects and in reconstructive surgery. (10072) Our studies have been concerned with its adaptation to thoracic surgery. At the present time 8 patients with pulmonary tuberculosis have been operated upon. Methyl methacrylate has been used as a filling material to maintain an extrapleural collapse. The results in these cases have been sufficiently gratifying to warrant its continued use and will be discussed in a later paper. The use of this material we believe will save from discard an operation which has interested surgeons since the procedure was first described in 1891. It fulfills a need not satisfied by paraffin, muscle, fat, oil gauze or air. It adds to the surgeon's armamentarium a single stage procedure which because of its simplicity can be used in complicated and poor risk patients with pulmonary tuberculosis.

SUMMARY

Experimental studies utilizing methyl methacrylate implanted into the pleural cavity and extrapleural space of 40 laboratory animals have been presented. The reaction of the pleura and extrapleural tissue has been demonstrated. Its

THE RH FACTOR-SEROLOGIC BACKGROUND AND CLINICAL APPLICATION

S. MILES BOUTON JR. M.D. M.S. Rochester New York

WHEN a foreign material such as, for example a disease-producing micro-organism enters the human body the latter is likely to respond with the formation of substances which destroy the invader. These substances, known as antibodies, usually function by agglutinating or by dissolving the foreign material. Antibodies may be absolutely specific in that they will attack only one particular antigen or toxin or micro-organism. Certain antibodies may be present in the body from birth so that the first invasion by the antigenic material is met by the already available defense force. This type of body reaction represents the process of immunization or if the antibodies are fully developed a state of immunity.

The antigen-antibody reaction which apparently is an attempt by nature to protect the body against noxious influences does not always proceed without damage to that body. If the total bulk of the affected foreign material or micro-organisms is sufficiently large, the agglutinating process within the bloodstream is apt to produce so much dead material in the form of coarse particles that capillaries may become obstructed and kidney function be impaired or if the dead material is broken down too rapidly a complicated systemic reaction to these "denatured" substances may set in manifested by chills, fever, flushing, chest and back pains, etc. If the foreign substance happens to be erythrocytes introduced with a transfusion of whole blood or of red cell resuspensions, there may be jaundice reflecting rapid destruction of the foreign red cells.

The so called A and B substances found either separately or together in the red blood cells of most human beings are in a sense antigens and they determine the four blood groups (A, B, AB, and O the last named being the group whose red cells contain neither of these two substances).¹ They are also called agglutinogens, because the

cells containing them are agglutinated (although they may be and frequently are hemolyzed i.e. dissolved) when brought into contact with agglutinins (antibodies) which are specific for the A or B substances and which are normally present in the serum of a part of the human race. Normally if an individual's red blood cells contain an agglutininogen his serum does not contain the corresponding agglutinin as there would then obviously occur destruction of the red cells within their own serum. That is to say anti A agglutinin is absent in individuals whose red blood cells contain A agglutininogen. The normally constant presence however of anti A agglutinin in the serum of a person with B cells renders that person a blood incompatible with that of an individual containing A (or AB) cells.

It is common knowledge that a transfusion reaction of severe type is practically inevitable if blood from a different group is introduced into the blood stream of any individual except one whose serum contains no agglutinins capable of destroying the injected red cells as it is this destruction of the foreign cells which almost invariably is the cause of the reaction. This is the reason we call an individual a "universal donor" ("blood group O") if his red cells contain no A or B agglutinogens so that the latter cannot be destroyed by pre-existing anti A or anti-B agglutinins in the serum of individuals receiving such a donor's blood. It is furthermore the reason we call an individual a "universal recipient" ("blood group AB") if his serum contains no anti A or anti B agglutinins, so that it cannot agglutinate or otherwise damage foreign red cells containing either A, B or A and B agglutinogens.

In pregnancy a mother may carry a fetus whose blood group will differ from hers because of inheritance from the father as father and mother do not, of course always represent the same group. One might therefore expect that the mother's already present anti A or anti B (or both) agglutinins would create havoc with the fetal red cells and red cell producing tissues, if the fetus has the corresponding agglutinogens within its cells, as such agglutinins readily pass through the walls of the placental villi which separate maternal and fetal blood. This actually does

¹From the Pathologic Laboratories, St. Mary Hospital, Dr. Bouton, director.

The A⁺ group includes subgroups (A₁, A₂, A₃) whose existence occasionally is responsible for so-called "intra group" incompatibility. These details do not contribute to this discussion and are therefore not considered further here.

occur, but only very rarely and the result may then be damage to the fetus in the form of "erythroblastosis foetalis," which may take the form—depending in part on the severity of the damage, in part on the organ or tissue chiefly affected in the infant, such as bone marrow or liver—of "hydrops foetalis," with death of the baby prior to or soon after delivery or of profound and progressive anemia, or of "icterus neonatorum" or possibly of a combination of these pathologic changes. (For purposes of didactic clarification only the familiar blood groups are invoked in this introductory discussion. More specific data follow.)

Almost all individuals are 'secretors,' that is to say, they possess the A or B substances not only in their red blood cells, but also—and actually in much greater concentration—in other tissue cells, and continue, moreover, to produce these substances in large amounts, so that they are even excreted in saliva and gastric juice (these fluids are the chief source of some commercially prepared A and B substances). When small amounts of anti-A or anti-B agglutinins are introduced into the bodies of 'secretors' gradually and by a route other than direct introduction into the circulatory system, they are readily neutralized or fixed by the abundant A or B agglutinogens within the body tissues before agglutination of the red blood cells, with their much weaker A or B concentrations, can occur. This is the reason why group incompatibilities of the A and B type between mother and fetus almost never occur. That is to say the red blood cells of secretors are surrounded, so to speak, by a defense wall which is breached, or rather circumvented only by the therapeutic device of intravenous administration of foreign blood in large quantity.

That trouble does to incompatibility of this type occurs at all is due to the fact that rare individuals are 'non-secretors,' that is to say they appear to possess A or B agglutinogens only in their red blood cells, which are thus exposed to the action of any anti-A or anti-B substance which may either through the placenta in the case of a fetus, or by transfusions in child or adult, get into the bloodstream. In other words, there is no available A or B substance elsewhere in the body to neutralize the anti-A or anti-B antibodies before they reach the red cells. In the fetus the effect may be erythroblastosis, in the recipient of a transfusion it may be a transfusion reaction.

The 'Rh factor' is an antigen which for all practical purposes may be considered to be entirely similar to the A and B substances, and, like these, it is also found within the red blood cells.

The two points of prime importance in considering the clinical problems related to this red blood cell factor are (1) that it exists only in the red blood cells that is to say *all individuals are non secretors* in regard to the Rh factor (2) that *there does not exist normally any anti-Rh antibody or agglutinin in human serum*.

The implications as to the first point are that any 'Rh-positive individual' (i.e. one whose red blood cells contain the Rh factor) is helplessly exposed to the destruction of his red cells if these are brought into contact with an anti-Rh agglutinin as his other tissues contain no Rh substance to neutralize such a specific agglutinin and thus to protect his red cells.

The implications as to the second point are that even though all Rh-positive individuals are nonsecretors, they are ordinarily in no danger at all as no normal individual has anti-Rh agglutinins in his blood. Consequently blood from both Rh positive and "Rh-negative (Rh-negative meaning simply absence of the Rh factor in the red blood cells by corollary group O blood might be termed AB-negative)" individuals can safely be given to Rh-positive or Rh negative individuals interchangeably with no risk whatever provided, of course, that donor and recipient are compatible as to their A and B groups. In other words, there is no need to consider Rh compatibility as far as *immediate danger* is concerned, in contrast to the situation as regards the A and B blood groups, and this fact explains also why ordinarily only the usual typing and cross matching procedures (for A and B substances) need be done to avoid transfusion reactions.

The Rh factor is dominant and follows the Mendelian laws of inheritance, that is to say in a mating of a genetically fully Rh-positive with an Rh-negative individual, the progeny will invariably be Rh positive. The Rh-positive progeny however may carry a "hidden" or recessive Rh-negative gene, and if such an individual is mated with an Rh negative individual, some of the progeny will be Rh-negative. An individual whose blood is Rh-positive and who carries only Rh-positive genes is "homozygot." An individual whose blood is Rh negative and who carries both Rh positive and Rh-negative genes is "heterozygot." If the blood of one partner in a mating, therefore, is Rh-positive and that of the other is Rh-negative the blood of the progeny will be either Rh positive in all children if the positive parent is homozygot, or in one half of all possible children if that parent is heterozygot.

In pregnancy there may be, and probably frequently is, some intermingling of maternal and

fetal blood through leaks in a traumatized placenta. In the case of an Rh negative woman carrying an Rh positive fetus such intermingling is at first quite unimportant in contrast to the situation of A or B incompatibility with a non-secretor fetus because the mother normally has no anti-Rh agglutinin with which to damage the fetal red blood cells. For this reason the first child in such matings is almost invariably normal, even if blood intermingling takes place in such an instance.

The introduction of Rh-positive red cells into Rh-negative blood will however initiate the production of anti-Rh antibodies so that prolonged or repeated contact of such blood with Rh positive red cells will eventually produce incompatibility. The latter will take the form of destruction of the Rh positive cells with resultant transfusion reaction on the part of the antibody-producing Rh-negative recipient of such cells, or damage to the fetus (e.g. erythroblastosis) in the case of antibodies formed by the Rh-negative mother entering the circulation of her Rh positive fetus, which as a non-secretor¹ in respect to its Rh factor cannot protect its red cells from the mother's antibodies by neutralizing the latter.

In other words, once sensitization of an Rh negative individual has occurred the status of that particular individual in regard to the Rh factor is the same as his or her status in regard to the A and B substances.

The initial lack of anti-Rh antibodies explains the fact that the first child in Rh-positive-Rh negative matings is normal and that transfusion reactions due to Rh incompatibility develop only gradually with only mild manifestations at first after repeated transfusions of Rh-positive blood into Rh negative individuals, and usually after a lapse of time necessary for the development of the anti-Rh antibodies. Of the white population about 87 per cent are Rh positive (negroes 92 to 95 per cent, Chinese and Japanese, 99 per cent). Actually the proportion of erythroblastic infants born of that population is considerably less than would be expected statistically because (1) there must (on the basis of existing knowledge) be direct contact between maternal and fetal blood to initiate development of anti Rh antibodies, presupposing placental leaks, (2) individuals differ in their ability to develop sufficiently large concentrations ("titers") of antibodies to cause damage (3) the relatively small number of women in our present population having more than one or two children naturally diminishes the likelihood of erythroblastosis.

On the other hand, the increased use of blood transfusions in present-day medical practice has increased the risk of sensitizing Rh-negative individuals by giving them Rh positive blood so that it occasionally happens that an Rh-negative woman will produce erythroblastosis in her first born because she received Rh positive transfusions previously, thus enabling her to develop anti Rh antibodies in preparation so to speak for her Rh positive child. Conversely if the husband of an Rh-negative woman is heterozygote the first 2 or 3 children may be Rh-negative so that the first Rh positive child, even though it represents the third or fourth pregnancy is just as safe as if it were the first born as there will have been no preceding antibody stimulation. Theoretically at least an Rh negative woman who as a child received intramuscular injections of Rh positive blood could conceivably be sensitized, but the likelihood of serious consequences of the form herein discussed is certainly remote.

An apparently complicating feature in the Rh picture is the more recently well established existence of several Rh types which may appear separately or in several combinations. This deserves mention in this connection only because the general medical literature occasionally refers to these subtypes by name, and because even if only in rare instances, it is possible for an Rh-positive woman to have an erythroblastic Rh positive infant on the basis of an Rh incompatibility. This would be because the father and mother happen to represent different Rh types, with the infant inheriting from the father an Rh factor absent in the mother's blood.

An additional complicating feature is the discovery of still another blood factor (more correctly red blood cell factor) which has been called the Hr factor in this country and is apparently identical with the St factor of British investigators. It is present (as determined to date) in the red blood cells of all Rh negative individuals as well as in those of individuals possessing certain of the Rh factors, that is to say about 75 per cent of the white population is Hr-positive (this includes the 13 per cent Rh negative portion as well as all Rh₁, Rh₂ and Rh types¹). The corresponding Hr antibody can contribute cases of incompatibility between Rh positive or Rh-negative fetus and Rh positive mother. Thus, it is necessary to know of this Hr factor and its antibody to avoid ignoring the possibility of incompatibilities when ordinary Rh

¹These last three are, of course, "Rh-positive"; see appended bibliography for terminology.

and anti-Rh testing seems to indicate freedom from danger.

To the ranks of Rh-positive—Rh-negative incompatibilities must therefore be added those occurring among Rh subtypes: the Hr positive—Hr-negative combinations; antibody action on nonsecretors in the regular Landsteiner groups, and so far not mentioned those relating to the M, N and P factors, the latter three long known in paternity testing but otherwise hardly of significance clinically.

The A and B nonsecretors, however chiefly of theoretical interest, were discussed earlier in this report only to furnish a more readily comprehensible groundwork for the discussion of the Rh and related problems. From the point of view of frequency incompatibilities induced by pregnancy or multiple transfusions remain chiefly an Rh positive—Rh-negative problem. Actually over 90 per cent of all cases of infant erythroblastosis occur with Rh-negative mothers, with the remaining less than 10 per cent of cases distributed among all the other aforementioned incompatibilities, and within this last-named minor group the Hr factor is probably responsible for the majority of cases.

Laboratory procedures for determining the Rh factors and their antibodies are similar to those long in use in determining standard blood groups, but are more difficult to perform and thus are subject to misinterpretation. A frequent error in many typing laboratories is the reporting of an Rh-positive individual as Rh negative, as many improperly controlled sources of such reports still use commercially advertised typing serum of animal origin which has the triple faults of (1) not reacting to all Rh types, (2) reacting poorly in most or many instances in which it should produce readable reactions and thus causing false negative readings, and (3) of producing false positive reactions in Rh negative infants. Aside from the last named occurrence no anti Rh typing serum should, theoretically ever give a false positive reading in a properly conducted test.

Many surprisingly weak reactions *in vitro* obtained from blood of women bearing markedly erythroblastic infants, and many false negative reactions in tests for anti-Rh antibodies have been explained by the concept of so called "blocking antibodies" (or "incomplete antibodies"), meaning substances in the serum to be tested which attach themselves to Rh-positive red cells (or more correctly to the Rh factor in those red cells) without causing agglutination thus preventing ordinary agglutinating antibodies from

producing a visible reaction. It is now becoming apparent that such blocking antibodies run parallel and may be identical with the anti-Rh antibodies which destroy Rh-positive red cells *in vivo* and that this test tube phenomenon may reflect artificial differences between reactions occurring within the bloodstream and those observed in the laboratory. This should also serve to explain at least in part why the customary "cross-matching" procedures for the regular blood groups were done these many years without discovery of the Rh factor and its antibody. Such differences are further indicated by the fact that the test tube reaction upon which we rely almost entirely in determining the Rh status is agglutination, whereas the reaction within the human body appears to be almost entirely one of hemolysis or at least of a combination of these two processes. Another potential source of confusion is the fact that Rh antibodies appear to react best at body temperature, i.e. they are "warm agglutinins," in contrast to anti-A and anti-B antibodies, which are cold agglutinins. Recently developed modifications of testing methods have largely overcome these handicaps, and Rh typing is now an adequately sensitive and dependable test with the right reagents and in trained hands.¹

A so called "biologic test" has been described and recommended, consisting of the introduction of a small amount of Rh-positive blood (e.g. 50 c.c.) into the circulation of an Rh-negative individual with testing of the latter's serum for evidence of subsequent hemolysis as an index of the presence of antibodies, but this procedure is considered by the writer to be reprehensible and at this time unjustified as it obviously tends to stimulate antibody production where there was none before. It is well established that minute amounts of Rh-positive red blood cells (such as are assumed, for example, to escape into maternal blood through damaged placental villi) may suffice to stimulate such a reaction.

The only good sources of spontaneously occurring dependable anti-Rh typing serum at present available are women who have recently given birth to erythroblastic infants, and, much more rarely, Rh negative individuals who have reacted to multiple Rh-positive transfusions. Such women should therefore, if healthy, be urged to contribute blood while their antibody titer is high and can be paid for such donations at the usual rates, as the Blood Grouping Labora-

¹The appended bibliography. It is essential, in this writer's opinion, that any laboratory or blood bank worker who performs anti-Rh typing read the papers dealing with these recent modifications of the test, as they represent a radical improvement over the original technique in the direction of both simplification and dependability.

tones in Boston (Dr. Diamond) will on receipt of such blood credit the sender with typing serum in proportionate amounts.

New sources of high titer typing substance in probably ample amount are now available obtained by fractionating serum from Rh-negative individuals with artificially stimulated anti Rh antibody production. This procedure is the same as, or similar in principle to that previously in effect for the production of high titer anti-A and anti B substances.

Rh-negative donors should of course be available through hospital lists for transfusions. It goes without saying that their standard blood groups must be established as well. Such lists cannot, however include women who have given birth to erythroblastic infants as their blood is apt to contain some anti Rh antibodies at all times.

In view of the comparative scarcity of dependable anti-Rh typing serum to date as well as of the fairly well established scope of the Rh problem in medical practice, it is at present neither desirable nor necessary to type every patient routinely for this factor. It is however proper that typing for the Rh factor be done prior to transfusions, in any female patient before and within the child-bearing age, in all pregnant women, in any postmenopausal woman with a history of having borne erythroblastic infants, and in any individual, male or female, who is to receive multiple transfusions over an extended period.

If a hospital patient is found to be Rh-negative, and if there is a history of previous unexplained transfusion reactions or of erythroblastic progeny the blood should automatically be examined also for anti-Rh antibodies. If a patient is Rh positive but if there is clinical ground for suspicion of blood incompatibility—as for example in a pregnant woman with a history of abnormal deliveries¹—her blood as well as that of the husband may be sent to Dr. Philip Levine or to Dr. Diamond for Rh subtyping and Hr typing at least until such time as hospitals generally may have available the necessary testing materials for determining Rh subtypes, Hr bodies, etc. in their own laboratories.

If anti Rh antibodies are found in a pregnant woman the physician should be notified and may then consider prophylactic procedures such as premature induction of labor or cesarean section.

¹The term abnormal deliveries should not include here miscarriages, such as anencephalics, as both embryologically and on the basis of clinical experience Rh incompatibilities cannot be incriminated for such conditions. This applies also to the relatively frequent miscarriages early in pregnancy.

In addition preparations should be made in advance of delivery for immediate checking of the infant's blood and clinical status with consideration of immediate transfusions of Rh negative blood, not from the mother. With such a treatment plan an anatomically normal-appearing infant, even if jaundiced at birth should recover completely. The chief risk is central nervous system damage from prolonged kernicterus i.e. jaundice of the cerebral basal nuclei but such risk is slight if jaundice is not permitted to become profound or to persist over a long period.

If a woman whose Rh status has not been previously determined is delivered of an infant which is jaundiced or edematous or unusually pale, and if the physician wishes to prove or rule out erythroblastosis due to a blood incompatibility without delay and with the fewest laboratory procedures, he should order a blood smear study on the baby (differential count) if this reveals erythroblastosis preparations for transfusions of nonmaternal Rh negative blood should automatically begin, with simultaneous determination of the baby's Rh and the mother's anti Rh status the latter tests to be done at that time chiefly to avoid the unlikely but possible accident of giving Rh negative and thus Hr-positive blood to an Rh negative baby carrying maternal anti Hr antibodies. When possible the placenta should be saved in all such cases for pathologic study.

There has been some published controversy as to the merits of giving erythroblastic infants Rh positive blood, on the assumption that the anti Rh antibodies transmitted by the mother to the infant might be more rapidly neutralized by the additional Rh-positive red cells. Even if this be granted (disregarding the clinical impression that such antibodies within the infant frequently are not free for complete neutralization at any one time, but are somehow "bound" and are released only gradually to act on the infant's red cells) it should be kept in mind that the neutralizing of such antibodies is taking place within the living infant, not in a test tube and that it represents a wholesale destruction of red cells within the body without substitution of non-affected red cells, so that an additional burden is placed on an already damaged liver as well as indirectly upon other tissues in the form, at least in part, of anemic anoxia. It would therefore seem more sound physiologically merely to replace the infant's own destroyed Rh-positive cells with indestructible Rh negative cells until the remaining maternal antibodies have diminished to the point of harmlessness, which will inevitably

SURGERY GYNFCOLOGY AND OBSTETRICS

be the case within a few weeks postpartum and usually occurs long before that. Obviously the older the baby the safer the infusion of Rh-positive red cells will be assuming there is still need for transfusions to combat a lingering anemia (due to delayed recovery of the baby's longer in evidence).

Lacking Rh-negative donors, the mother's Rh negative red cells may be infused into the infant after they have been separated from their serum and are resuspended in saline as the maternal anti-Rh antibodies exist only of course in the serum and can be eliminated by such separation. The father's blood is obviously not suited, as it is factors inherited from the father which are in the first place responsible for the damage to the infant.

Attention is called to the possibility of increased danger of hemorrhagic damage to an erythroblastic fetus during prematurely induced labor. Whether this represents an actual hazard in practice remains to be seen but it must be considered in weighing the relative merits of labor induction versus cesarean section.

The practicing physician's greatest problem is that of advice to Rh incompatible parents. He must first assemble and evaluate all pertinent data, i.e., past clinical and laboratory evidence if available, of the mother's "antibody potential as reflected in antibody titer and severity of damage to previous offspring and the possibility that the husband may be heterozygote. The latter information can usually be obtained in such cases, as it will be remembered that there appears to be a definite relationship between occurrence of the Hr factor and the absence of any or presence of heterozygote Rh factors in the blood, which makes it possible to attempt laboratory determination of heterozygote individuals by the combined use of anti Hr and specific anti-Rh sera. Rh typing of the husband's parents and siblings or of previous children if there are several, may permit determination of heterozygosity make-up of the husband without recourse to Dr Diamond's laboratory, as, for example, one Rh-negative sibling of the husband or one Rh-negative child is sufficient to prove such status.

Advice to parents may include warning against becoming pregnant immediately following delivery of an erythroblastic infant (to permit antibody level in the mother to subside) and should include urgent suggestion for prenatal

antibody checking and possibly psychological preparation for cesarean section or premature induction of labor. It is furthermore essential that the mother refrain from nursing an erythroblastic child, as her milk will contain the antibodies responsible for the infant's disease. On the other hand, if the husband is heterozygote or the woman a antibody potential appears to be low, the possibility of entirely normal children should be kept in mind by the physician and should be explained to the parents in advance, so that the latter will not lose confidence in the advancing physician because of apparent discrepancies between his expressed fears and their experience. The event of an entirely normal pregnancy following discussion of their problem.

To compensate for the superficial consideration in this discussion of the technical and scientific (specifically genetic) details on which this subject is based, the appended list of selected original reports is recommended as representing complete and authoritative information, beyond the needs of the practicing physician but obligatory reading for a complete blood bank or responsible laboratory.

NOTE. Additional experience since this paper was written (Ayimma, 1945) has confirmed my opinion that it is not good practice to give more than very small amounts of fluids intravenously to premature infants. If fluids are required, subcutaneous administration probably comes with it the least danger of cardiovascular embarrassment. This practice deserves mention here because of the tendency in some quarters to give blood "prophylactically" to infants in whom erythroblastosis has not been demonstrated, but in whom its possible development is anticipated. If labor has been induced or cesarean section performed prematurely on the basis of high and rising antibody titer in the mother the prematurity of the infant must be considered as a deterring factor when intravenous fluid administration, especially of whole blood, is contemplated. If there is evidence of already developing erythroblastosis, the condition of already developing treated red cell suspension in saline intravenously and of plasma substitution (the latter of course, as non-specific supportive therapy and provider of plasma proteins) is recommended.

"INFLAMED AND INJURED TISSUES NEED REST

TODAY when so much emphasis is being placed upon the ambulatory treatment of fractures of the lower extremity and upon early rising after abdominal operations after operations for hernia and after childbirth it may be worth while to recall some of the principles of Hunter of Hilton and of Hugh Owen Thomas and their insistence upon the importance of rest in wound healing.

The names of John Hunter and his older brother William are familiar to every medical student that of Hilton probably much less so. John Hilton (1807-1878) began the study of medicine at Guy's Hospital when only 17 received his diploma at the age of 21 and then entered the dissecting room as demonstrator of anatomy. For 17 years he worked in the dissecting room and postmortem room before he was appointed at the age of 38 assistant surgeon to the hospital and lecturer on anat-

omy. In 1863 after the completion of a series of lectures before the Royal College of Surgeons he published these lectures in a small volume *Rest and Pain* which exerted a profound influence both on his contemporaries and on succeeding generations of surgeons on no one more than on his admirer Hugh Owen Thomas. His essential philosophy he expressed very clearly at the close of his fourth lecture.

"By regarding this subject of physiological and mechanical Rest in what I conceive to be its proper professional light, the surgeon will be compelled to admit that he has no power to repair directly any injury. It will induce him to acknowledge, in all his milky that it is the prerogative of Nature alone to repair the waste of any structure. He will thus realize that his chief duty consists in ascertaining and removing those impediments which obstruct the reparative process, or thwart the efforts of Nature, and thus enable her to restore the parts to their normal condition.

To secure the rest which he considered of fundamental importance in wound healing (as of course did John Hunter and many others before him) he constantly drew upon the extensive anatomical knowledge acquired during his long years of apprenticeship in the dissecting room. His emphasis upon the importance of pain as an indication both to diagnosis and to treatment, and his method of providing rest for inflamed tissue are pointedly brought out in his discussion on inflamed joints in Chapter VII.

I may remind you that when a joint becomes inflamed it is painful and difficult of movement it becomes involuntarily fixed by Nature's own process, thus securing comparative rest to the interior of the joint. Indeed we may lay it down as an axiom that Nature instinctively renders an inflamed joint comparatively fixed and flexed.

Rest and Pain. Course of Lectures on the Influence of Mechanical and Physiological Rest in the Treatment of Accidents and Surgical Diseases, and the Diagnostic Value of Pain. By the late John Hilton, F.R.S., F.R.C.S. edited by W. H. A. Jacobson, M.A., M.B., M.Ch. (Oxon.) F.R.C.S. London: G. Bell and Sons, Ltd., 1934.

SURGERY GYNECOLOGY AND OBSTETRICS

He goes on to describe the innervation of joint and surrounding muscles that permits and brings about the rigid muscle contractions that immobilize and protect the affected joint. The obvious corollary is the careful splinting that provides a substitute and relief for the contracted muscles and permits the painful spasm to subside and still insure the needed rest.

The same principle of relief of painful and spastic muscle contraction resulting from inflammation of surrounding tissue is exemplified by many types of cases—fractured bones suppurating joints osteomyelitis nerve injuries rectal and anal ulceration, etc. etc. A somewhat broader application of the principle of rest that carries its own connotations is his amusing account of a patient with a chest injury (Lecture V.I)

A physician, residing not very far from me had under his care a patient who had received a blow upon his chest by a fall upon the part and as he was, after several days, still suffering a good deal of pain in breathing the physician asked me to see him in reference to the possibility of fractured ribs. I could find no fracture but I observed that the patient had a most worrying wife. She was incessantly talking to him day and night, and there were continual tensions between them upon domestic affairs. I suggested to the physician that the sole cause of the pain was, in all probability the sole cause of the constantly moving the injured or bruised soft parts by using his chest and lungs in speaking. All I recommended was, that he should hold his tongue, and have his chest bandaged. I requested that his wife would not say a word to him, but would provide him with a slate and pencil so that he might write down all his desires. From that time he got quickly well by local rest.

One believes that Weir Mitchell would have approved of this treatment.

Perhaps better known to the surgeon of today than Hilton is his follower and admirer that doughty little man with peaked cap and ever present cigarette to whom every worker in the field of bone and joint surgery is so greatly indebted Hugh Owen Thomas (1834-1891) Thomas went still further than Hilton

in his insistence on enforced uninterrupted and prolonged rest.

His message to the surgeons of his time was that they did not understand the meaning of the word rest. Hilton he said fixed a limb in a splint, and believed he had given it rest. Immobilization he held to be the first requisite but it must be applied in such a way that the diseased part was not compressed, nor the normal circulation of the limb in any way interfered with. All forms of plaster-splint accumbent and several others he abandoned them at an early stage of his practice. Pressure he held, was a form of restlessness or irritation. If he applied a stiff or elastic bandage to a diseased knee joint, so as to compress and surround it, he held that in so far as he lessened the movement of the joint he assisted repair but in so far as he compressed it he hindered repair until all trace of unsoundness had disappeared from the joint and then that point being reached, the cure would be completed by the gradual return of natural voluntary movements.

Keith in his delightful chapter on "The Principles and Practice of H. O. Thomas in *Masters of the Maimed*" goes on to cite his application of the principle of rest in a condition with which we rarely connect the name of Thomas—obstruction of the bowel

"The treatment of the case I have selected for an example has been placed on record by his nephew Sir Robert Jones.

"I remember well how Mr. Thomas called the relatives together and told them he was going to make a fight for the patient's life. He urged them to be loyal and to help him and to add to his persuasion, he threatened them with a coroner's inquest if they gave the patient anything without express permission. Above all things the patient was to have no milk the foot of the bed was to be elevated to lessen the pressure in the abdomen a morphia injection was given and nothing but sips of water with a little arrowroot. For the first few days he visited the patient five or six times a day. Almost immediately the vomiting was reduced to about once in twenty-four hours the patient became easy and slept, but the abdomen was tense. Twice he performed paracentesis (for the relief of pressure) being careful not to allow the trocar to remain in the intestine longer than a few minutes, for fear of a fistula. On the twenty-fourth day at intervals, a very little fat was passed on the twenty-sixth large quantities, and

Masters of the Maimed, the Anatomical and Physiological Principles Underlying the Treatment of Injuries to Muscles, Nerves, Bones, and Joints by Arthur Keith, M.D. (Abern.), F.R.C.S. (Edn.), and Abner H. H. London: Henry Frowde; Hodder & Stoughton; Grafton University Press, 1919

later in the day a few small scybala. Again during the night a copious pulsatious motion and this again followed for three days by prodigious quantities of thin faecal fluid.

From the method in which that case was treated we see that rest was to be applied with the meticulous care and rigidity of a Calvinistic doctrine. Rest was to be secured first by sedatives—to place the bowel at ease and relieve pain the bowel was to be restrained from all manner of work by absolute starvation he declared he had never seen starvation cause death in a case of intestinal obstruction however prolonged. The bowel was not to be disturbed by any act whatsoever such as the giving of enemata or 'rectum tickling' as he most unprofessionally phrased the practice. 'Nature,' he said 'is late in working a relief and patience is needed. His critics said his treatment of intestinal obstruction was not new and modern surgeons will declare it to be bad. His medical critics, however were wrong opium and starvation had been often prescribed and employed in such cases rest had been enjoined but Thomas was the first to apply rigidly and completely the principle of rest as a logical system to such conditions, and to carry it out in the form of enforced uninterrupted, and prolonged rest.

Many illustrations of the emphasis on rest in modern therapy can be quickly called to mind. The treatment of tuberculosis by rest of the body and rest of the involved lung is the very basis of modern therapy. Wangenstein, Miller and Abbott introduced an effective method of combatting intestinal obstruction that exemplifies the principles Thomas stressed so clearly. Orr applied the teachings of Hilton and Thomas to the care of osteomyelitis and gave a new meaning to the words 'enforced uninterrupted and prolonged rest.' More recently Dragstedt has applied the principle to the treatment of inflamed and ulcerated gastric and duodenal mucosa by removing the irritating influence of excessive gastric secretion through division of the vagi.

Accurate and painstaking as were the experimental observations of Hunter the studies of Hunter and Hilton in dissecting room and post mortem room and the clinical observations of all three men neither Hunter nor Hilton nor Thomas had the opportunity of following the process of wound healing by microscopic studies of tissue from experimentally produced

wounds. It is of interest then to note that in reports of such studies by many workers (Harvey, Howes, Mason and Allen, and others) the lag period of wound healing is constantly emphasized and the fact that during this initial period of from 4 to 6 days the strength of the wound depends solely upon the suture material used. Mason and Allen¹ have shown that in the case of sutured tendons the tendon ends become swollen, soft, almost gelatinous and that tension applied during this early period can result only in cutting through of suture material and separation of tendon ends. Howes and Harvey² have stated:

From this study one is able to say that fibroplasia starts abruptly at the fourth day and proceeds with decreasing velocity until a maximal strength for this phase of healing is reached around the twelfth to the fourteenth day and that by the sixth approximately one third and by the eighth approximately two thirds of this strength is obtained. This, of course, is readily checked against and correlates with surgical experience. This phase of fibroplasia has been studied in wounds of all tissues in which the normal tensile strength is greater than the maximum of the fibroplastic process and the velocity curves of fibroplasia are identical in type.

The fact that at a later period during the process of healing physiologic tension and activity provide a helpful stimulus to sound healing of soft tissues of tendon and of bone was well recognized by Hunter, by Hilton and Thomas and again has been confirmed by many well controlled experimental studies. Until time has elapsed for fibroplasia to be gone—and its beginning will be influenced as Howes has stated 'by careful surgical technique with the minimizing of infection and contamination in the wound and with the insertion of small amounts of suture material'—the 'injured and inflamed tissues need rest. It is obviously not the answer to every problem. It is a principle of wide application and of far reaching importance. SUMNER L. KOCH

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

WE are happy to welcome the *Journal of the History of Medicine and Allied Sciences* to the company of surgical and medical journals. The motive for this journal and its purpose are so clearly set forth by Editor George Rosen that we repeat a few sentences in introductory pages that we repeat a few sentences in human development. Every situation that man has faced and every problem that he has had to solve have been the product of historical developments and processes.

To understand our own society and to be capable of playing an intelligent rôle in shaping our own civilization, we must have knowledge of the actions of the past.

During the past seventy five years a large part of the medical profession has turned away from the history of medicine. We sincerely believe that this trend has resulted in a serious loss for a profession which by implication approach each time it writes or speaks of the case history. In part, also, the onus for this trend may be attributed to medical historians who were not always able to make medical history the living, dynamic thing that we believe it to be. We do not want to cultivate medical history as a mere search for antiquities, as a kind of hunt for curios, but rather as a vital integral part of medicine.

No one would have agreed more whole heartedly with Dr. Rosen than Oiler Welch, Cushing and Cutter—men to whom the memories and achievements of the great doctors of the past were living and integral parts of our heritage and our present day attainments.

A partial list of the table of contents of the first number will give the reader a clue as to the scope of the new journal. Some Galenic and animal sources of Vesalius the London years of Benjamin Waterhouse a note on William Blake and John Hunter pharmacopoeias as witnesses of world history the two earliest dentistry woodcuts, Bernardino Mon-taña de Monerrate education in 17th century Spain.

The editors of *SURGERY GYNECOLOGY AND OBSTETRICS* extend best wishes to the new journal and high hopes for its success.

The Manual of Surgical Anatomy by Tom Jones and Willard Shepard was prepared under the auspices of the Committee on Surgery of the

Division of Medical Sciences of the National Research Council. It is one of a series developed by the States Army and Navy with compact presentation of necessary information in the field of military surgery.

The objectives are plainly set forth in the foreword. According to Major General Kirk, in the surgery of trauma great demands are made upon the surgeon's knowledge of anatomy, in the treatment of traumatic injuries under the exigent conditions of war a concise atlas of applied anatomy is required to permit "a rapid visual review of any part of the body and the proper surgical approaches to the various regions."

In a second foreword Vice Admiral McIntire commends the artists for the preparation of "line drawings which for accuracy and simplicity may be considered unsurpassed. These comments and commendation record the chief characteristics and the successful nature of the *Manual*, they merely require elaboration.

The figures are arranged in the following order, and with the indicated coverage in pages: head and neck (33 pages) thorax, abdomen, and pelvis (49) upper extremity (40) lower extremity (30). The section on Illustrations is followed by a 35 page explanatory index, which is essentially a glossary of names many of them and structures pictured, but legends. Many of the figures are executed in such a way that surgically important deep structures are projected (usually in color) in relation to superficial, palpable landmarks. For example, in purely anatomical pictures, cerebral ventricles, dural venous sinuses and tributary veins are shown in interrelationship and in their relationship to cerebral gyri and to bones of the skull accessory air sinuses and salivary glands in relationship to regions of the face palmar synovial sheaths, to skeleton and to surface markings vessels and nerves, to bones of the extremities. In anatomoclinical illustrations, the body are grouped in sets for the major divisions of the body the same very serviceable scheme is employed on even more ambitious scale. In the plate depicting pericardotomy, for example, the series begins with transverse section showing the anatomical route of approach to the heart this is followed by one recording skin and muscle incisions in relation to the costal cartilages another to expose costal cartilages then, successively picture, pericardium and heart with coronary vessels. Thoracotomy, sympathectomy laparotomy lumbar sympathectomy block arthroplasties for all major joints synovectomy

The Manual of Surgical Anatomy by Tom Jones and Willard Shepard was prepared under the auspices of the Committee on Surgery of the

JOURNAL OF THE HISTORY OF MEDICINE AND ALLIED SCIENCES. NEW YORK: HENRY SCHENCK, 1941. A MANUAL OF SURGICAL ANATOMY. Prepared under the auspices of the Committee on Surgery of the Division of Medical Sciences of the National Research Council. By Tom Jones and W. C. Shepard. Philadelphia and London: W. B. Saunders Co., 1941.

to all long bones commonly involved in fractures are illustrated with equal ingenuity. Ingenuity & hand made economy is here an able supporter. Surface landmarks, topographical succession in transected part, and structures serially encountered in the incisional route are almost invariably shown in a single plate of multiple figures with carefully selected labelling of crucial elements and in a pattern of arrangement reflecting the best in artistic taste and the highest in pedagogic value.

All drawings were done with the line technique. They are uniform, strikingly clear and invariably crucial.

It is earnestly to be hoped that when the needs of the Army and Navy have been met, the book will be made available for regular commercial sale to medical schools. The undersigned would encourage his own students to purchase this excellent manual.

BARRY ANSON

THE two volumes entitled *Clinical Cystoscopy* by Lowman E. McCrea can be recommended without reservation to everyone interested in urology. The make-up of the books is exceptionally well done. The type is large and easy to read, the paper is of unusually good quality with a glossy surface that reproduces very well the photomicrographs, drawings, diagrams, pictures and actual color photographs. There are 667 illustrations of which 106 are in color.

The first volume concerns the cystoscope its history and use in diagnostic procedures of the bladder and ureters. In its seventeen chapters can be found reference to nearly everything that is known in modern urology. The section on cystoscopic photography is proof of the author's creative genius in perfecting a camera that will take color pictures intravesically. The actual color photographs of the bladder mucosa both normal and diseased, are accurate and life-like. Nothing like them can be found in any similar publication. This contribution to the specialty is the result of many years of patient labor and is definitely worth the effort.

The second volume is divided into fifteen chapters, eleven of them are devoted to the kidney. Renal anomalies, function tests, injuries, infections, calculi, cysts and tumors are treated in an interesting and able manner. Chapter XXII discusses medical disease of the kidney, a subject not usually covered in a urological text. The last three chapters deal with urology in women and children and urological roentgenography. At the end of each volume is an excellent bibliography covering the subjects discussed in the respective chapters.

The author has been faithful in his intention to present a concise yet complete compendium of every disease observed or diagnosed by the cystoscope. He has presented his material in such a manner as to

make one feel that urology is an important field of medical endeavor. The accuracy of modern methods of diagnosis and treatment is clearly emphasized. We feel that Dr. McCrea has made an important contribution to modern urological literature.

EDMUND CROWLEY

THE interesting monograph entitled *History of Surgical Anesthesia* by Thomas E. Keys has an introductory essay by Chauncey D. Leake and a concluding chapter on the future of anesthesia by Noel A. Gillespie. The excellent introductory comment of Chauncey Leake reviews his personal contacts with anesthesia. He stresses the lack of fundamental knowledge regarding the basic concepts of pain, and marvels at the accomplishments in the relief of pain regardless of the gaps in our knowledge still unbridged.

Thomas E. Keys was reference librarian for the Mayo Clinic and, as a major with the medical corps was assigned to the Cleveland branch of the Army Medical Library. These unusual contacts together with the author's keen historical perception have made possible this exciting human story of the development of surgical anesthesia.

The work includes a revision of the five essays which were published in *Anesthesiology* revision of chronology and a selected list of references arranged by author and subject.

The author has made it his responsibility to correct many of the errors which have crept into the history of anesthesia and to try to present with an unbiased judgment, based on historiography the main contributions. The work will provide for the medical student an interesting picture of the drama of progress in anesthesia during the past 100 years. It will provide the anesthetist with a résumé and bibliography and the discerning anesthesiologist with an up-to-date compilation of many historical facts of anesthesia and related subjects. It can be highly recommended as a concise volume of factual information regarding the history of surgical anesthesia.

MARY KARP

THE second edition of *Nitrous Oxide-Oxygen Anesthesia* by Clement is enlarged by the addition of 30 pages and 22 engravings.

The more important additions or changes in the second edition concern the nitrous-oxide theory of anesthesia, the technique of administration of nitrous-oxide-oxygen, the practical and applied physiology of anesthesia, the mechanism and treatment of shock, the dangers of prolonged oxygen deficiency and details as to the use of the nasopharyngeal airway in dental practice. The discussion of shock as it concerns the anesthetist has been markedly improved in this new edition. The section on physiology has been enlarged and improved through

THE HISTORY OF SURGICAL ANESTHESIA. By Thomas E. Keys. New York: Schuman's, 1945.
NITROUS OXIDE-OXYGEN ANESTHESIA; McCrea—Clement. NEW THEORY AND TECHNIQUE. By F. W. Clement, M.D. and M. C. (A.U.S.) ed. Philadelphia: Lea & Febiger, 1945.

CLINICAL CYSTOSCOPY: A TREATISE ON CYSTOSCOPIC TECHNIQUE, DIAGNOSIS, PROCEDURE, AND TREATMENT. By Lowman E. McCrea, M.D. F.A.C.S. Philadelphia: F. A. Davis Co. 1945.

inclusion of recent advances in research. Considerable space has been devoted to a discussion of airways and particularly the endotracheal technique in anesthesia. As in the first edition there is an excellent review of the signs and symptoms which develop under nitrous-oxide anesthesia and a helpful chapter devoted to the significance of cyanosis.

Full consideration has been given to preoperative medication and this subject is now set apart in a special section. Basic instructions for the administration of nitrous oxide-oxygen are not markedly changed from those of the first edition.

The author emphasizes by repetition the need for preoperative medication for supervision of anesthesia by a well trained and experienced anesthetist for active co-operation of surgeon with anesthetist and for an alert anesthetist who can recognize promptly the symptoms of impending shock and institute proper therapy.

MARY KARP

IT is always delightful, after an absence of months, to greet old and admired friends and when they appear in a jaunty new outfit and still sparkling with enthusiasm and helpful ideas our admiration is redoubled. The new sixth edition of Homans' *Text book of Surgery* brings also an unwelcome reminder of the inexorable passage of time: the distinguished author is now Clinical Professor of Surgery Emeritus, nine of the twenty two original contributors have passed into the Great Beyond—all in the fifteen short years since the appearance of the first edition.

It is hardly necessary to point out again what a felicity of style and expression, what delightful glimpses of historical background and what a rich sense of humor Homans has added to a comprehensive grasp of surgical principles and technique to make this volume an outstanding contribution to the literature of surgery. He has made the task of the surgical student a pleasant one and has broadened his outlook in every direction.

A TEXTBOOK OF SURGERY. By John Homans, M.D. 6th ed. Springfield, Ill. Charles C. Thomas, 1947.

"That remarkable old genius Hippocrates" "not until Vesalius weakened mechanically at the superwork of the *Almagest*" (p. 6) are typical Homansisms phrases that bring sparkle and zest to lure the reader on and make the beginner realize how fascinating the subject of surgery can be.

It is always difficult in reading a new edition of so comprehensive a treatise to gauge accurately the changes and revisions that have been made. As Homans says in his preface "the value of chemotherapy has been affirmed—the advantage of complete immobilization of wounded limbs has been supported—and transfusion of whole blood has been found superior to the use of even the best of the blood substitutes. These statements indicate a few of the lines along which changes and additions have been made. Fortunately sufficient time has passed since the introduction of the sulfonamides and penicillin to give the author an opportunity to make considered statements concerning their indications and use (the sulfonamides) tend to sterilize the blood stream—but they do not kill the bacteria in the initial lesion which still requires surgical drainage" (p. 73).

the local use of such agents in abdominal wounds will probably be entirely abandoned (Allen) Intravenous administration of the sulfonamides results in a rapid high concentration of these drugs in the peritoneal fluids. Foreign body reactions occur in the abdominal cavity after local use of the less soluble members of the group" (p. 958). Penicillin is referred to frequently particularly in connection with spreading infection of cellular tissue, septic sore throat, osteomyelitis, infections of the brain and meninges, of the ear and eye, of the pleural cavity and of the genitourinary tract.

Blood vessel suture blast, the immersion syndrome, the treatment of burns, the surgery of the sympathetic and parasympathetic system (usually comprehensive) external fixation of fractured bones, the technique of skin grafting—are only a few of many subjects which have been enlarged upon or included for the first time.

The bibliographical index—a distinctive feature of Homans' Textbook—again directs the reader quickly and accurately to sources where he may find more detailed discussion and information of specific subjects. All in all the interested reader cannot fail to realize how well the whole field of surgery has been covered and what a distinctive contribution Homans has made to surgical literature.

OUTLINE OF PROGRAM FOR CLINICAL CONGRESS AP- PROVED BY BOARD OF REGENTS OF AMERICAN COLLEGE OF SURGEONS

A T a meeting in Hot Springs, Virginia, on April 1 the Board of Regents of the American College of Surgeons approved a preliminary program for the Clinical Congress, to be held at the Waldorf Astoria in New York City from September 9 to 13 in accordance with the following outline

Monday September 9

- 10:00 General Assembly for Surgeons and Hospital Representatives, Grand Ballroom
- 1:30-3:00 Panel Discussion, Empire Room
- 3:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
- 3:00 Hospital Conference, Sert Room.
- 3:00 Surgical Film Exhibition (General) Grand Ballroom.
- 3:00-5:30 Assembly of Initiates and reception, Grand Ballroom.
- 3:00-5:00 Panel Discussion, Empire Room
- 8:00 Presidential Meeting and Convocation, Grand Ballroom

Tuesday September 10

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
- 10:00 Hospital Conference, Sert Room
- 9:30 Surgical Film Exhibition (E.E.N.T.) Jensen Suite
- 9:30 to 12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
- 10:00 Surgical Film Exhibition (General) Empire Room.
- 11:00 Group Clinical Conferences
Ophthalmology
Otorhinolaryngology
- 1:30 to 3:00 Panel Discussion, Grand Ballroom
- 3:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
- 3:00 Hospital Conference, Sert Room.
- 3:00 Symposium on Fractures and Other Traumas.
- 3:00 Surgical Film Exhibition (General) Empire Room
- 3:30 to 5:00 Panel Discussion, Grand Ballroom.
- 7:00 Surgical Film Exhibition (E.E.N.T.) Empire Room
- 7:00 Hospital Conference—Trustees, Sert Room.

- 8:00 Scientific Session, General Surgery Grand Ballroom.
- 8:00 Scientific Session, Panel Discussion, Ophthalmology Jensen Suite.
- 8:00 Scientific Session, Otorhinolaryngology Le Perroquet Suite.

Wednesday September 11

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
- 9:30 Hospital Conference, Sert Room.
- 9:30 Surgical Film Exhibition (E.E.N.T.) Empire room.
- 9:30 to 12:00 Forum on Fundamental Surgical Problems, Grand Ballroom
- 10:00 Surgical Film Exhibition (General)
- 11:00 Group Clinical Conferences
Ophthalmology
Otorhinolaryngology
- 12:00 Meeting of Governors of College, Jensen Suite.
- 1:30 to 3:00 Panel Discussion, Grand Ballroom.
- 3:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
- 3:00 Symposium on Cancer Empire Room.
- 3:00 Surgical Film Exhibition (General)
- 3:30 Hospital Conference, Sert Room.
- 3:30 to 5:00 Panel Discussion, Grand Ballroom
- 7:00 Surgical Film Exhibition (E.E.N.T.) Empire Room.
- 7:30 Hospital Conference, Sert Room.
- 8:00 Scientific Session, General Surgery Grand Ballroom
- 8:00 Scientific Session, Joint E.E.N.T. Empire Room.

Thursday September 12

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
- 9:30 Hospital Conference, Sert Room.
- 9:30 Surgical Film Exhibition (E.E.N.T.) Empire Room
- 9:30 to 12:00 Forum on Fundamental Surgical Problems, Grand Ballroom.
- 10:00 Surgical Film Exhibition (General) Empire Room
- 11:00 Group Clinical Conferences
Ophthalmology
Otorhinolaryngology
- 1:30 Adjourned Meeting, Governors, Grand Ballroom.
- 2:45 Annual Meeting, Fellows, Grand Ballroom.

- 2:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
 3:00 Hospital Conference, Sert Room
 3:00 Panel Discussion—Graduate Training in Surgery Jensen Suite.
 3:30 to 5:00 Panel Discussion, Grand Ballroom.
 5:30 Surgical Film Exhibition (General), Empire Room.
 3:30 National and Regional Fracture Committees, Le Perrequet Suite.
 7:00 Surgical Film Exhibition (E.E.N.T.), Empire Room
 8:00 Scientific Session, General Surgery Grand Ballroom.
 8:00 Scientific Session, Ophthalmology Empire Room.
 8:00 Scientific Otorhinolaryngology Sert Room.

Friday September 13

- 9:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
 9:30 Surgical Film Exhibition (E.E.N.T.) Empire Room.
 9:30 to 1:00 Forum on Fundamental Surgical Problems, Grand Ballroom.
 10:00 Surgical Film Exhibition (General) Empire Room.
 11:00 Clinics, Demonstrations and Clinical Group Conferences, Selected local hospitals.
 Group Clinical Conferences, Obstetrics and Gynecology Sert Room.
 1:00 to 4:00 Plastic Surgery 4 U.Blu. Room
 Neurological Surgery Assembly Room M N
 Thoracic Surgery Jensen Suite.
 Urology Le Perrequet Suite.
 Fractures and Other Traumas, Grand Ballroom.

Orthopedic Surgery Carpenter Foyer and Dining Room.

2:00 Surgical Film Exhibition (General), Empire Room.

This outline, as stated previously is preliminary only, and certain important changes are under consideration which, if adopted, will be announced in the next issue. Next month it will also be possible to publish a much more detailed program.

COMMITTEE ON ARRANGEMENTS

The Committee on Arrangements for the Clinical Congress consists of the following surgeons from the New York area.

Howard Patterson,
Chairman
 Frank Glenn,
Secretary
 Frank Adair
 Albert H. Aldridge
 Thomas M. Brennan
 E. Jefferson Browder
 George F. Cabill
 Henry W. Cave
 Ralph Cobb
 Edward J. Donovan
 Merrill N. Foote
 John H. Garlock

Charles A. Gordon
 George J. Heuer
 J. William Hinton
 George H. Humphreys
 William F. MacFee
 John H. Malhotra
 W. Barclay Parsons
 Otto Pickhardt
 Thomas H. Russell
 Raymond P. Sullivan
 Howard C. Taylor, Jr.
 William Crawford White
 Philip D. Wilson

Blood amylase, activity in pancreatitis and other diseases, simple diagnostic aid, 115 cor 404

Blood levels, Chemotherapy and control of infection among victims of Coconut Grove disaster 151

Blood vessels, Reflex sympathetic dystrophy 36. anatomical dissections, Saphenous venous tributaries and related structures in relation to technique of high ligation, based chiefly upon a study of 550 anatomical dissections, 53. Persistence of vitelline (omphalomesenteric) artery as clinical problem, 570. Use of compression in treatment of injuries, ed. 618

Bone, Reflex sympathetic dystrophy 36. long. Single-stage operative method of management of chronically infected, ununited fractures, 44. tumors of. Osteogenic sarcoma, II. Roentgenographic interpretation of growth patterns in bone sarcoma, 81. graft, Interosseal, in spiral fusion after disc removal, 215, fixation, Electrolytic absorption of due to use of stainless steel of different composition for internal, 319. Topical penicillin treatment of established infection in compound fracture wounds, 557. Chronic osteomyelitis complicating war compound fractures, evaluation of 123 patients treated by early secondary closure, 573

Bronchopneumonia, following ether anesthesia in obstetrics, 427

Bronches, Acquired esophagotracheobronchial fistula, 87

Burns, Chemotherapy and control of infection among victims of Coconut Grove disaster 151. Treatment of report of 155 cases, 311. thermal, Clinical and pathologic study of kidney in patients with, 652

CALCULUS, microscopic, in kidney. Origin, frequency and significance of 275

Cancer. Accidental transplantation of, in operating room with case report, 212, of rectum, Resection of with reconstruction of canal through perineal approach, 223. of cervix, new technique for interstitial implantation of radium into parametrium, 512; Is biopsy of neoplasms dangerous? experimental study 567

Cardioid, Large retroperitoneal metastasis so called, of small intestine, 675

Carcinoma, bladder. Indications for roentgen therapy of recognition of suitable cases, 29. of fallopian tube, Primary 199. lymphatic spread, Retrograde, of "rectosigmoid region, Its influence on surgical procedure, 434. of rectum. Restoration of continuity versus cure in, ed. 490

Chemotherapy and control of infection among victims of Coconut Grove disaster 151; Treatment of burns, report of 155 cases, 311

Chest, War injuries of, 13. wound of Ipsilateral spastic rectus abdominis in purely thoracic wound, ed. 356

- Bronchopneumonia following ether anesthesia in obstetrics, 457
 Coconut Grove disaster. Chemotherapy and control of infection among victims of, 52
 Colon. Segmental resection of lesions occurring in left half of, with primary end-to-end aseptic anastomosis, correction, *see* 238
 Compression. Use of in treatment of injuries, *ed.* 6 8
 Curare. Use of in anesthesia for thoracic surgery preliminary report, 220
 Cyst. Pilonidal, analysis of on consecutive cases, emphasizing treatment by radical excision, primary closure and penicillin therapy 694

DIAGNOSIS, Osteogenic sarcoma, II. Roentgenographic interpretation of growth patterns in bone sarcoma, 8
 Gastroscopic, roentgenologic, Leukosarcoma of stomach, its, and its possible relation to pernicious anemia, 239
 Disc, intervertebral, Intercorporeal bone graft in spinal fusion after removal, 15
 Disease, Amino acids in therapy of, parenteral and oral administrations compared, 3
 Ductus arteriosus, patent, Operative closure of, 13
 Duodenum. Observations on radical surgery for lesions of pancreas, 623

EAR, Composite free grafts of skin and cartilage from, 53
 Electrolytic absorption, of bone due to use of stainless steel of different composition for internal fixation, 3 9
 Embolism, pulmonary. Venous thrombosis and, *ed.* 23
 Empyema, War injuries of chest, 23; thoracic, Decortication in acute, 71
 Epithelioma, Vasoepithelial anastomosis by production of permanent fistula with use of stainless steel wire, 387
 Failure of urethral union, 471
 Esophagus, Acquired esophagotracheobronchial fistula, 87
 Correction of esophageal atresia and tracheo-esophageal fistula by closure of fistula and oblique anastomosis of esophageal segments, 318
 Ether, anesthesia, Bronchopneumonia following, in obstetrics, 457
 Exophthalmos, Studies on, produced by thyrotropic hormone, I. Study of produced by various thyrotropic hormones and influence of testes on, 200 II. Changes induced in various tissues and organs (including orbit) by thyrotropic hormone and their relationship to, 600 III. Further study of changes induced in fat by thyrotropic hormone (these reactions associated with) 7 7
 Extremities, lower. Reflex sympathetic dystrophy 36
 lower, Single-stage operative method of management of chronically infected, ununited fractures, 44
 lower Saphenous venous tributaries and related structures in relation to technique of high ligation, based chiefly upon study of 53 anatomical dissections, 53
 lower Treatment of varicose veins, 322

FALLOPIAN tube, Primary carcinoma of, 99
 Observations on treatment of adenocarcinoma of uterus, 386
 Fat droplets, Studies on exophthalmos produced by thyrotropic hormone, III. Further study of changes induced in fat by thyrotropic hormone (these reactions associated with exophthalmos) 717
 Femur. Gunshot fractures of femoral shaft, 9
 Fibrosarcoma, Is biopsy of neoplasms dangerous? experimental study 507
 Flap, function, Surgical repair of deep branch of radial nerve, 305

Fistula, Acquired esophagotracheobronchial, 87
 tracheo-esophageal, Correction of esophageal atresia and, by closure of and oblique anastomosis of esophageal segments, 318
 Flap, pedicled fascial, Repair of large abdominal defects by 144
 pedicle, "Hitts, strikes and cuts" in use of, for nasal restoration or correction, 367
 Foot, amputation, Discussion of controversial points in amputation surgery 495
 New method of treatment for severe fractures of os calcis, preliminary report, 67
 Forearm, wounds of Surgical repair of deep branch of radial nerve, 305
 Fractures, infected, ununited, Single-stage operative method of management of chronically 44
 Gunshot, of femoral shaft, 9
 Chronic osteomyelitis complicating war compound, evaluation of 5 patients treated by early secondary closure, 573
 Fracture wounds, Topical penicillin treatment of established infection in compound, 557
 Frothite, human, Subcutaneous heparin in Pitkin menstruum for treatment of experimental, 36

GALL bladder. Observations on radical surgery for lesions of pancreas, 63
 Spontaneous gastrocholedochal biliary fistula, 73
 Gastrointestinal tract, Preliminary report of method for prevention of leakage of intestinal anastomosis, experimental study 475
 Gelatin, I. travemous, for nutritional purposes, clinical and experimental studies, 25
 Grafts, skin and cartilage, Composite free, from ear, 233
 Gynecology. Clinical study of early postoperative embolization in, 348

HAND infections, Diagnosis of acute flexor tenditis tenosynovitis, 10
 Heel, New method of treatment for severe fractures of os calcis, preliminary report, 67
 Heparin, Subcutaneous, in Pitkin menstruum for treatment of experimental human frothite, 36
 Hernia, inguinal, Utilization of Henle's Ligament, iliopectic tract, aponeurosis transversus abdominis and Cooper's Ligament in inguinal herniorrhaphy report of its consecutive cases, 480
 Heterotopia, Pancreatic, review of literature and report of 4 authenticated surgical cases, of which 3 are clinically significant, 537
 Hormone, thyrotropic, Studies on exophthalmos produced by I. Study of exophthalmos produced by various, and influence of testes on exophthalmos, *see* II. Changes induced in various tissues and organs (including orbit) by and their relationship to exophthalmos, 600, III. Further study of changes induced in fat by (these reactions associated with exophthalmos), 717
 Hypoplastic plexus, Pelvic autonomic nerves in male, 96
 Hypoglycemia, Massive islet cell tumor of pancreas without, 30

ILEUM Large retroperitoneal metastasis from os calcis carcinoma of small intestine, 675
 Infection, bone, Gunshot fractures of femoral shaft, 9
 Chemotherapy and control of among victims of Coconut Grove disaster 51
 Study of value of local sulfathiazole in operative wounds in prophylaxis of, 323
 Inguinal region, anatomy of, Utilization of Henle's Ligament, iliopectic tract, aponeurosis transversus abdominis and Cooper's Ligament in inguinal herniorrhaphy report of 162 consecutive cases, 480

Injection treatment, Treatment of varicose veins, 332
 Injuries, Use of compression in treatment of, ed 678
 Instruments and apparatus, prostheses, Electrolytic absorption of bone due to use of stainless steels of different composition for internal fixation, 319 hysterosat, Observations on treatment of adenocarcinoma of uterus, 386 Devine clamp, Preliminary report of method for prevention of leakage of intestinal anastomoses, experimental study 475 prostheses, Discussion of controversial points in amputation surgery 495
 Intestines, anastomoses, Preliminary report of method for prevention of leakage of experimental study, 475 obstruction of Persistence of vitelline (omphalomesenteric) artery as clinical problem, 579 Large retroperitoneal metastasis from so called carcinoid of small, 675 Spontaneous gastrointestinal biliary fistulas, 723

JEJUNUM Effects of pedicle jejunal transplants in stomach on Mann-Williamson dogs, 194

KIDNEYS, Thoracoabdominal wounds, review of 270 cases, 64 calculi Origin, frequency and significance of adenocarcinoma, 275, Postcaval ureter with description of new operation for its correction, 549 Clinical and pathologic study of in patients with thermal burns, 632 Urinary incontinence due to bilateral ectopic ureters, 712

LEG, amputation, Discussion of controversial points in amputation surgery 495

Leucosarcoma, of stomach, its roentgenologic and gastroscopic diagnosis and its possible relation to pernicious anemia, 339

Ligament, Utilization of Henle's, iliopectic tract, aponurosis transversa abdominis and Cooper's, in inguinal herniorrhaphy report of 163 consecutive cases, 480

Liver, Thoracoabdominal wounds, review of 270 cases, 64 Blood amylase activity in pancreatitis and other diseases, simple diagnostic aid, 115, cor 494

Lungs, War injuries of chest, 13, Thoracoabdominal wounds, review of 270 cases, 64 Decortication in acute empyema thoracis, 71 Chemotherapy and control of infection among victims of Coconut Grove disaster 151 Use of curare in anesthesia for thoracic surgery preliminary report, 229, Bronchopneumonia following ether anesthesia in obstetrics, 427 Experimental surgical pulmonary collapse 735

Lymphatic system, Retrograde lymphatic spread of carcinoma of "retrocolicoid region," its influence on surgical procedures, 434

Lymphogranuloma venereum, Rectal strictures due to with reference to Pouchet's excision operation, 449

MALARIA, Ruptures of malarial spleens unassociated with external trauma, 731

Martin, Franklin H., Reorganization of Surgical Publishing Company of Chicago, ed. 232

Mast operation, Traumatic aneurysm, 57 years after 1 Medical Department, U S Army European Theater of Operations, Military surgery 1944-1945, 261

Metabolism studies, Amino acids in therapy of disease, parenteral and oral administrations compared, 131

Method, copper sulfate Sahli Practical observations on, for determining specific gravities of whole blood and serum 405

Methyl methacrylate (Lucite) implants, Experimental surgical pulmonary collapse, 735

Mortality rates, in World War I and II U S Army-European Theater of Operations, 1944 1945 261

Muscles, rectus abdominis, Ipsilateral spastic, in purely thoracic wound, ed 356

NATIONAL Research Council, Contaminated Wound and Burn Projects, Chemotherapy and control of infection among victims of Coconut Grove disaster 151

Nerve, Lateral aberrant thyroid, 705

Nerve, radial, Surgical repair of deep branch of 305 Pelvic autonomic, in male, 598 Primary suture of 632

Nervous system sympathetic, Reflex sympathetic dystrophy 36, sympathetic, Intrathoracic tumors of, 683

Newborn, Rh factor serologic background and clinical application, 743

Nitrogen balance, Amino acids in therapy of disease parenteral and oral administrations compared, 131

Nitrogenous substances, Intravenous gelatin for nutritional purposes, clinical and experimental studies, 25 Intravenous amino acids, protein digesta—accuracy of terminology ed 105

Nose, Composite free grafts of skin and cartilage from ear 353 "Flits, strikes and cuts" in use of pedicle flaps for nasal restoration or correction, 367

Nutrition, Intravenous gelatin for nutritional purposes, clinical and experimental studies, 25

OBSTETRICS, Bronchopneumonia following ether anesthesia in, 427

Operating room technique, Accidental transplantation of cancer in, with case report, 212

Orbit, Studies on exophthalmos produced by thyrotropic hormone, I. Study of exophthalmos produced by various hormones and influence of testes on exophthalmos, 290, II Changes induced in various tissues and organs (including) by thyrotropic hormone and their relationship to exophthalmos, 609 III Further study of changes induced in fat by thyrotropic hormone (tissue reactions associated with exophthalmos) 717

Os calcis, New method of treatment for severe fractures of preliminary report, 671

Osteomyelitis, Chronic, complicating war compound fractures, evaluation of 125 patients treated by early secondary closure 573

Ovary Primary carcinoma of fallopian tubes, 199 Observations on treatment of adenocarcinoma of uterus, 386

PAIN low back, Intercorporeal bone graft in spinal fusion after disc removal, 215

Pancreas, Massive islet cell tumor of without hypoglycemia, 301 Blood amylase activity in pancreatitis and other diseases, simple diagnostic aid, 115, cor 494; heterotopia of Pancreatic, review of literature and report of 41 authenticated surgical cases, of which 25 were clinically significant, 527 Observations on radical surgery for lesions of 633

Pancreatitis, Blood amylase activity in, and other diseases, simple diagnostic aid, 115, cor 494

Parotid gland, Adenocarcinoma, cylindroma type of clinical and pathologic study of 21 cases, 342

Patella, Patelectomy in military service report of 19 cases, 423

Penicillin, Decortication in acute empyema thoracis, 71

Topical, treatment of established infection in compound fracture wounds, 557, Chronic osteomyelitis complicating war compound fractures, evaluation of 125 patients treated by early secondary closure 573

Plenoidal cyst, analysis of 100 consecutive cases, rim phasizing treatment by radical excision, primary closure and, therapy 604

Perineum, Resection of rectum with reconstruction of canal through perineal approach, 283

- Physical therapy Treatment of burns, report of 55 cases, 35
- Mucosal cyst, analysis of 100 consecutive cases, emphasizing treatment by radical excision, primary closure and penicillin therapy, 694
- Pitkin menstruum, Subcutaneous heparin in, for treatment of experimental human frostbite 396
- Plasma proteins, Intravenous gelatin for nutritional purposes, clinical and experimental studies, 35 level. Amino acids in therapy of disease, parenteral and oral administrations compared, 3
- Plasma volume determinations, Correction of blood loss during surgical operations, 47
- Pneura, Use of curette in anesthesia for thoracic surgery preliminary report, 39
- Pneumolysis, Experimental surgical pulmonary collapse, 735
- Postoperative care, Early rising, statistical study of hospital complications, 485. Inflamed and injured tissues need rest, ed. 749

BURNS

Collective Review

CHARLES C. LUND M.D., F.A.C.S. ROSS W. GREEN M.D. F. H. LASKEY TAYLOR, Ph.D.,
and STANLEY M. LEVENSON M.D. Boston, Massachusetts

IN comparison to the great economic importance of burns in all parts of the world in times of peace as shown for instance, by the more than 5,000 deaths per year in the United States alone, scientific studies concerned with them have always been relatively small in number and relatively poorly supported. The present war with its lavish use of gasoline and oil as motive power and the use of bombing as a weapon has stimulated the Allies to mobilize national resources and many scientists for comprehensive studies of the consequences of fire. This report will be concerned for the most part with the developments in Great Britain, the British Dominions, and the United States. Nothing is known to the authors concerning any studies on burns in Germany and Japan or in their satellite or conquered countries during the 5 years since Belgium has been cut off from the Allied World.

DEFINITIONS

A. Depth of burn.

For many years the universal custom in the United States and Canada and the preponderant custom in Great Britain has been to classify burns according to their depth into three categories as follows: first degree, simple erythema; second degree, partial destruction of the skin; but without

destruction of all the deep epithelial cells; and third degree, destruction of the full thickness of the skin. In the French literature prior to the war the Dupuytren classification was used by most authors. In this classification the definition of first degree burns is the same. Dupuytren's second and third degree burns correspond to superficial and deeper second degree burns as just classified and Dupuytren's fourth, fifth, and sixth degree burns correspond to the third degree just defined. Converse and Robb-Smith have recently classified the depth of burns in a manner extremely useful to any one who is evaluating the results of treatment. This classification divides the burns in such a way that the deep second degree burns and mixed second and third degree burns, both of which types heal slowly under any treatment, are no longer tabulated with the more superficial second degree burns which heal easily with almost any form of treatment. They use a name rather than a number to describe a burn. Their names, descriptions, and prognoses are compared in Table I with commonly accepted meanings of the degrees of the Dupuytren and American classifications. This excellent classification has been suggested so recently that it has not been used by other authors as yet. However there has been a widespread use by American authors of the subdivision of the "second degree burn" into superficial and deep second degree burns. Admittedly the newly proposed class of mixed burns will contain only a small proportion of the cases in any series, but these burns are a distinct and important entity. The authors of the present review will use this new classification in order to avoid any confusion that may possibly arise by the use of either older classification.

From the Burn Assesment of the Surgical Services and the Thorndike Memorial Laboratory and the Second and Fourth Medical Services (Harvard) of the Boston City Hospital and the Departments of Surgery and Medicine of the Harvard Medical School. The work described in this paper was done under a contract, recommended by the Committee on Medical Research and Training, between the Office of Scientific Research and Development and Harvard University.

This review comprises the major part of a review prepared for the Belgian-American Foundation of New York and the Fourn de la Fondation Française de Bruxelles for distribution in French translation to all the doctors of Belgium. This is one of a series of reviews named Actualités Médico-Chirurgicales.

TABLE I—CLASSIFICATION OF DEPTH BURNS

Degeyres	American	Converse and Rehn-Smith		
Degree	Degree	Name of Burn	Description	Prognosis
1st	1st	Epidermal	Erythema followed by desquamation	Heal well
2nd	2nd	Dermal	Blistering and superficial destruction of the dermis	Heal well
3rd	3rd	Deep dermal	Destruction to deep layers of dermis	Heal slowly
Mixed 1st & 2d	Mixed 2nd & 3rd	Mixed burns	Small areas of deep dermal alternate with small areas of deep burns	Heal slowly
4th, 5th & 6th	4th	Deep	Destruction of whole thickness of the skin into or beyond the fat	Heal with difficulty. Prognosis uncertain unless grafted

At the occurrence of the burn and for several weeks thereafter it is frequently not possible to estimate correctly the depth of the injury. Many small blebs, some broken and some intact, with an external oozing of plasma, visible pink corium, and minimal subcutaneous edema indicate a dermal burn. A dry dead white brown or charred appearance with beginning subcutaneous edema indicates a deep burn. The appearance of other burns is intermediate between those described and these burns cannot be classified until epithelization or granulation have become evident. Dingwall and Patey and Scarff have attempted to solve this difficult problem. The former has observed his cases with ultraviolet light and a filter after intravenous sodium fluorescein injections, and the latter have studied serial microscopic sections of burns and also the naked eye appearance after the application of Van Gieson's stain. Both these methods are promising but neither has been evaluated, as yet by other workers.

Until Dingwall's or Patey and Scarff's suggestions have been found to be widely applicable burns should not be classified until healing or epithelization is well under way. Most of the recent authors have been cognizant of this, but there are a few recent articles which indicate that the authors think they can estimate the depth of a burn when the burn is first seen. This is shown, for instance, by a statement that a given form of treatment has "prevented the burn becoming a deep burn."

B Area of burn

Although the proportionate area of skin burned has long been recognized as useful as a guide to the prognosis of burns, it has now become of even greater importance as a guide to treatment. One of the first needs of a patient with a serious burn is adequate plasma therapy. After a close estimate of the area of the burn and of its proportion to the total area of skin has been made, a formula may be used to estimate the approximate amount of

plasma needed during the first day of treatment. Such a formula will be presented later.

Long prior to its use for this purpose, Weidenfeld and Berkow (16) made studies directed toward simplifying the recording of and comparison of burns. Both studied by actual measurement the surface areas of the parts and of the whole surface of many individuals of all ages. As a result of this work, Berkow's table¹ is constantly in use in this country and Great Britain for the study of burns, and all recent important studies have used it. Both Weidenfeld and Berkow pointed out that the proportionate area of the parts of an individual vary widely between birth and adult life. Peck and Davis, Seeger and Wallace also pointed out this fact, but the majority of important publications that have stressed the use of Berkow's table have mentioned only his table for adults.

While in search of a suitable diagram and standards for the recording of burns in children, Lund and Browder found that Berkow's tables for adults and children, which have been perfectly satisfactory for work up to date, are oversimplified and contain certain errors that should, if possible, be avoided in the more exact studies that are now being made in many clinics. The results of their study are seen in Figures 1 and 2, which are reproduced from their article. It should be noticed particularly that the area of the face makes up a relatively large proportion of the total skin area of infants when compared to the findings in adults, and is counterbalanced by the small area of the infant's thighs and legs. Also, the proportion of skin of all other parts is essentially unchanged from one age to another. The area determined for the trunk is much smaller than the area assigned to it by Berkow.

PATHOLOGY

A Local.

Burns either injure or kill cells. The cell membranes become abnormally permeable to

various substances. A very superficial burn will result in the injury of the most superficial cells but no cells will be killed. A deeper burn will result in the death of cells to a certain depth, and underlying these cells there will be injured but viable cells.

The response to the mildest burn or the response to a more severe burn at the point in depth where the burn is minimal is dilatation of the capillaries and the finer arterioles and venules with markedly increased blood flow through all of the three following, a brief period of vasoconstriction.

In some mild first degree burns this is the only demonstrable result. In slightly more severe burns the capillary walls are injured and leak blood plasma into the tissues. At the same time other cell membranes leak and there is an abnormal exchange of cell constituents into the tissue spaces and of tissue fluid into the injured dead cells. If the burn is deep enough red cells in the capillaries may be damaged or even ruptured immediately.

Because of the leakage of plasma from the capillaries, the tissue spaces become distended with fluid. This fluid if near the surface, forms blisters under the epidermis at first and after rupture of the blisters continues to pour out for more or less lengthy periods of time. The fluid that represents capillary leakage at deeper levels finds its way slowly into the lymphatic system (83). A result of this is greatly increased lymph flow from the area. Both the lymph and the blister fluid coming from the burned area have long been known to be similar in composition to the plasma prior to the onset of infection (134).

Pressman and his associates have recently studied this problem and have found constant amounts of albumin and variable amounts of globulin in blister fluid. Glenn Peterson and Drinker and Cope and Moore (45) have studied the flow pressure and composition of lymph after burns. The amounts of fluid that may be lost through into or under a burn are frequently large, as will be indicated later. It is also extremely important to remember that while the burned skin is permeable to plasma it is also permeable in the other direction. Absorption of various substances will be considered in detail later.

At once, after a burn repair processes start. When the damage is minimal the repair consists of the return of normal tone to the blood vessels of the cessation of leakage, and the absorption of any fluid that is present in the tissue spaces. If

cells have been killed the dead cells are removed by lysis and phagocytosis. In case the burn is deep this process takes place only at the border between the living and the dead cells and the dead cells are sloughed off in masses or sheets. The intercellular collagen resists digestion more than the cells and the collagen fibers keep the slough attached until they are finally digested at the point of demarcation between the living and the dead parts of the fibers. After the slough has separated repair of the denuded surface takes place by a new growth of epithelial cells from islands of living cells, from the edges of the wound or by successful skin grafts. If the derma is destroyed and healing occurs by ingrowth from the edge, the repair may be quite imperfect because a very thin sheet of epithelium covers the dense connective tissue that results from the final contraction of the granulation tissue. Besides being very thin this scar epithelium is poorly nourished and poorly attached to its base. The repair process may be delayed as a result of local treatment, of infection or of various deficiencies, such as those of iron protein or vitamins, but cannot be stimulated to heal except by creating optimal conditions so that there is no interference with cell division and cell maturation.

B Pathology of red blood cells

Inevitably when sufficient heat penetrates to a depth in the tissue where there are capillaries, some red blood cells are injured. In vitro studies have shown that thermal injury of these cells occurs between 52 degrees and 65 degrees C. (167) Lysis frees the hemoglobin which is in the cells.

The occurrence of hemoglobinemia and hemoglobinuria after severe burns has long been known as an indication of a very serious burn. In general, the former is seen only in deep burns of 10 per cent or more of the body area and the latter in such burns of 30 per cent area or more. Hemoglobinemia when it occurs, is found to be most severe immediately after the burn and to decrease gradually during the first 24 to 72 hours. A long duration of hemoglobinemia in the plasma does not occur following burns. Hemoglobin does not appear in recognizable quantity in the urine unless it is present in large amounts in the plasma. Its duration in the urine depends on its duration in the plasma. The hemoglobin in the plasma and the urine has been shown to be for the most part oxyhemoglobin mixed with traces of methemoglobin (167). There is no evidence that burns ever release any form of myohemoglobin such as is found after crush injuries."

Shen, Ham, and Fleming have confirmed the work of Spiegler and others who found that the blood of the burned patient with hemoglobinemia contained many abnormal red cells, such as fragmented cells and spherocytes with an increased osmotic fragility. No hemolysis or agglutinins are found (28). Hemoglobinemia and hemoglobinuria are discussed with the kidney

C Blood platelets

In very severe burns thrombocytopenia of severe degree occurs. MacDonald and her associates have shown that the platelet count decrease to less than 50,000 within 16 hours of injury and the level may remain low for 60 days. This confirms older work of Salviolelli to confirm that of Welti and Locke

D. White blood cells

Leucocytosis appearing immediately after the injury and continuing for variable lengths of time has long been known as a constant finding in nearly every burn of moderate or severe extent. The early leucocytosis is usually directly proportional to the severity of the burn. Later the leucocytosis varies directly with other evidences

of infection such as fever. In a few cases of severe burns a leucopenia or relative leucopenia has been observed between the first and the sixth days. During the early leucocytosis or leucopenia the differential white blood count may show an increased proportion of nonfilamented leucocytes and other degenerative changes in the leucocytes, and the presence of myelocytes and the absence of

eosinophils. Van Duyn has recently expressed the opinion that these degenerative changes are the result of a toxic injury to these cells and that this proves that there is toxemia associated with burns that cannot be accounted for by injury, hemocoagulation or infection. In his opinion this toxemia is caused by some substance absorbed from the burned area.

E. Renal function

Impairment of renal function as evidenced by anuria, oliguria, and azotemia is a conspicuous feature in the early course of patients with severe burns. Albumin, hemoglobin and casts are frequently found in the urine of these patients, while large numbers of white or red blood cells are rare. Reversible azotemia is associated with transient oliguria occurs frequently even in burns of only moderate severity. This phenomenon is similar to that found following shock of any type and is presumably due to a decreased blood flow through the kidney during shock. The blood flow through the kidney may be decreased to one-twentieth of the normal at a time when the general blood flow is reduced only to one-half (11). This is true particularly in burn shock in which the vasoconstriction at any given peripheral blood pressure seems to be significantly greater than in other types of shock. Van Slyke has shown that a severe reduction in renal blood flow for many hours without reduction in the flow to the rest of the body may be followed by anuria and death of animals.

It has also been suggested that the kidney failure of burns is caused by the hemoglobin that is excreted in some cases (19). This is suggested by the histological changes in the kidney which are similar to the changes in patients with hemoglobinuria due to causes other than burns. The principal histological changes are the presence of pigmented (hemoglobin) casts, nonpigmented epithelial casts and necrosis of the tubules. At autopsy on patients who survived more than 60 hours following regeneration of the tubular epithelium is also seen (26).

Although it is well established that intra-vascular hemolysis from a variety of causes is frequently followed by failure of kidney function the mechanism of this action and the causative agent or agents in the hemolyzed blood remain to be determined. It has been suggested that neither oxyhemoglobin or free hemoglobin is the toxic agent (19) but rather methemoglobin (20) or possibly the same hemoglobin may be the causative agent. It is possible that a third cause

is involved that is that these agents may be more toxic to or only toxic to a kidney with an impaired flow of blood.

The problem of the toxicity of hemolyzed blood is intimately linked with the question whether alkalinization of the urine prevents renal damage. The first urine of patients with severe burns is almost invariably strongly acid and immediate administration of alkali to the patient has been recommended. The purpose of this alkalinization is to prevent precipitation of the products of the destroyed red cells in the renal tubules in the presence of an acid urine (10). In most patients with hemoglobinemia and hemoglobinuria, when first observed have already been present for at least an hour before this examination is made or before any alkalinization is possible. Consequently there are no actual data available as to the prophylactic value of this treatment in human beings and no experiments with animals are known. Although no evidence for or against the value of alkalinization on entry for this purpose has been found after careful studies at the Boston City Hospital and the point is still controversial, we feel that it should still be used. Alkali treatment of burns for other purposes is not new but has recently been brought into great prominence by Rosenthal and by Fox. It will be discussed further under shock.

F. Pathology of the liver

From the time of Bardeen's work there have been reports of liver necrosis in burns. Bardeen described a diffuse injury to all the liver cells. Following Wilson and his coworkers' report in 1938 there began to be many reports of a different type of injury characterized by focal necrosis of the central cells of the lobules. A very marked polymorphonuclear leukocytic infiltration of the necrotic areas. Wilson queried at that time whether the then popular tannic acid treatment had some causal relationship to this change. In 1941 Wells, Humphrey, and Coll, by clinical and experimental work, definitely showed that this peculiar necrosis was due to tannic acid poisoning. This has been confirmed by others (23). It has also been shown that the immediate application of the tannic acid hastens the amount of its absorption and therefore the degree of liver injury (23). The forms of treatment that induce slow tanning such as tannic acid baths or tannic acid jellys are therefore much more dangerous than rapid tanning with 5% acid and 10% silver nitrate solutions (17 & 193). However, as Lee points out there is no liver necrosis encountered in burns treated with

acid is used but very few cases have been reported in which bland ointments, saline solution or dry dressings have been used (63 133 176) A case of marked central necrosis of the liver has been seen when triple dye was used for the surface treatment (115)

Late liver damage as evidenced by jaundice and decreased prothrombin concentration from 2 to 6 months after injury has been seen in a number of patients who have received human plasma or whole blood (114) All of these patients recovered. Clinically these cases are similar to and probably identical with cases of homologous serum jaundice which are due to the transmission of a virus of infectious hepatitis in serum plasma or blood (172)

G Pathology of the kidney

Scattered pathological studies of the kidney in patients dying of burns have been made (131 184 194) the most recent being a report by Goodpastor *et al.*, who found a close correlation between clinical and laboratory evidence of kidney dysfunction, extent of deep burn severity shock, hemoglobinuria, and renal morphologic changes at postmortem. The most consistent anatomical changes were the following on microscopic examination the glomeruli were normal and the tubules showed varying degrees of necrosis affecting principally the ascending and descending portions of the loops of Henle. Pigmented casts in the tubules were a constant finding in these cases. These casts have been considered to be derived from the breakdown of red cells, although direct proof of this is lacking. Some support to this conception is lent by the demonstration of hemoglobin, oxyhemoglobin, and methemoglobin in the blood and urine of all severely burned patients. In addition casts composed of degenerated tubular epithelial cells have been found in most of the same cases. Evidence of regeneration of tubular epithelium was seen in most of the patients in this class who survived more than 72 hours.

In contrast with the marked microscopic abnormalities, the findings of gross examinations were essentially normal. In a few cases the kidneys were swollen the cortices pale, and the medullae dark red, presenting prominent black, brown or purple red streaks corresponding to the papillae. These streaks corresponded to the tubules filled with pigment casts.

It is quite apparent from the description that the renal changes are similar to those following hemolytic blood transfusion reactions, traumatic shock crush injury and hemolytic sulfonamide

reactions. Goodpastor *et al* believe that the important etiologic factors of injury to the kidney in burns are the presence of marked hemoglobinemia hemoglobinuria and severe shock.

H Pathology of the gastrointestinal tract

The occurrence of ulceration of the intestinal tract following burns has been recognized for over 100 years. Curling directed special attention to this subject in 1842. Harkins (87) has recently reviewed the reported cases. The occurrence of gastrointestinal ulceration following burns is more common than coincidence would allow. A severe third degree burn often of a sloughing septic type is most apt to result in such a complication. A decreased incidence of this complication may come from a more aseptic handling of burns. The only other therapeutic considerations are the realization of the possibility of these ulcers and institution of the proper medical or surgical treatment of them as is indicated. Up to the present time, no acute ulcer following burns has been treated surgically.

Children and females are more often affected but this may be because they are more frequently burned. The symptoms of such an ulcer may be of rapid onset and include epigastric pain of melena and hematemesis. The average length of life in ninety four cases with necropsy collected from the literature was 15.4 days.

The ulcer involved the duodenum alone in seventy-one cases, the stomach in five cases. The ulcer cases, and both organs in multiple thirty cases, and single fifty seven times and multiple thirty four times. Hemorrhage was twice as apt to be a fatal factor as perforation and the pancreas was often exposed and the pancreaticoduodenal artery eroded. Thirteen reports of gastrointestinal ulceration with recovery are also mentioned by Harkins.

The etiology of the ulcers has not been determined. Various theories involving nervous, infectious, toxic, and embolic factors have been suggested (87). Necheles and Olsen studied the gastrointestinal secretions following burns, as the salivary, pancreatic, and biliary outputs were considerably diminished. The gastric secretions however were increased by several hundred percent with an associated increase in gastric motility. These writers believe that these observations bring forth "new light on the problem of Curling's ulcer."

Actual ulceration of the gastrointestinal tract has been seen only once in the Boston City Hospital series of 60 recent autopsies. Therefore, Levenson *et al* (115) think that it is a rare complication.

tion under the present modes of treatment. However the same observers as well as Mallory and Brickley have confirmed the older observations of congestion of and diffuse hemorrhage from the upper gastrointestinal tract in human beings. They made these findings only in those patients with extensive burns and severe shock. In Leverson's series there were 6 instances of these findings but as mentioned above only 1 Curling's ulcer. Similar changes have been found more frequently in experimental animal, particularly the dog and cat (75). These changes were accentuated by preburn and postburn hyperinization of the animals (75).

I. Respiratory tract

Up to 1912 injury of the respiratory tract had occasionally been reported as a complication of burns. At that time injury of the respiratory tract assumed great prominence since the majority of the victims of a fire at a Boston night club (The Coconut Grove) in which about 500 people lost their lives, had suffered damage to their respiratory tracts. The clinical and x-ray aspects of these cases will be discussed later. Pathological examination (130) revealed that the respiratory damage was essentially that of a laryngotracheobronchitis. Three patients who were dead on arrival at the hospital were examined at autopsy and all showed an intense but nonnecrotizing hemorrhagic tracheitis and bronchitis, and presented heavy voluminous lungs from the cut surfaces of which fluid in large amounts could be expressed. Microscopic examination confirmed the presence of acute pulmonary edema and demonstrated in the upper tracheobronchial tree a serohemorrhagic exudation without significant leukocytic infiltration (110).

In individuals who died after varying periods of time in the hospital, (1 to 12 days) severe necrotizing tracheobronchitis was found with the formation of a pseudomembranous membrane. Many of the respiratory passages were occluded by the pseudomembrane and visceral muoid and sanguineous exudate. Pulmonary damage consisted chiefly of congestion, edema and scattered areas of atelectasis, emphysema, hemorrhage and pulmonary infarcts. Pneumonia developed in the upper lobes and was usually infrequently associated with scattered necrotizing lesions.

The etiology of the lesions has not been clearly shown. It is assumed that the respiratory tract was primarily an indirect part of the burn and that particularly when resulted from the burning of the face and neck. The victims were

inhaled enough to render them unconscious sustained the severest respiratory damage (111). Similar pathological findings were reported in the Cleveland Clinic fire of 1928 (141). However special fires involving many people are necessary to cause this type of lesion. Gumpert *et al.* found 19 cases at autopsy on 10 patients dying of sporadic burns and Leverson *et al.* (113) observed many patients who recovered in their series of 600 sporadic burns. The only factor in common to all of the patients was that they had inhaled much smoke. A few cases resulted from the inhalation of smoke from a fire involving only a bed.

J. Adrenals

Weiskotten stated in 1917 that the most prominent and characteristic necropsy findings in patients with burns were changes in the adrenal glands. He described swelling, necrosis, and periaxial edema with hemorrhage in all cases of more than 24 hours duration. Microscopically there was necrosis of the cortical cells. Since then others (17, 142, 79) have reported similar findings in some but by no means all, burn syndromes. The most recent report is that of Mafora and Brickley who found focal necrosis of the adrenal gland in 2 cases in which death occurred from 2 to 3 days after the burn. They mentioned swelling of the coils of the outer portion of the cortex with accumulation of serous exudate in the space produced, pyknotic nuclei, acidophilic necrotic of the adrenal cells, and infiltration with polymorphonuclear cells.

The finding of depleted cortical hypoadrenalism, largely cholesterol, following burns has been recently confirmed by Sayers *et al.* who state that in burns the adrenal glands are stimulated to exhaustion by the adrenotropic hormone of the anterior pituitary lobe. Markens (90) has stated similar findings and conclusions.

K. Spleen and lymph nodes

Bardeen described swelling and necrosis of the lymphoid nodules of the lymph nodes pericardial lymphoid tissue and spleen which he considered characteristic of burns and indicative of trauma. These observations were made in children who died from 4 to 935 hours after injury. In a recent review of 95 burn autopsies Baker drew attention to the presence of karyorrhexis (fragmentation) of the cells in the lymph nodes. He found that high degrees of karyorrhexis were found only in children dying within 3 days more than minimal karyorrhexis was observed in a single subject beyond 3 days.

Baker raises the questions whether the karyorrhexis is pre-existent to the burn i.e. a normal finding in children and whether its absence later is not the abnormal feature. Further studies are required to clarify this point.

L. Heart.

Kayashima found that after experimental burns in rabbits, electrocardiograms were abnormal. The waves were low in amplitude, the T wave was flattened out, and the ventricular complex tended to be monophasic. Similar changes were observed by the same author in 12 Naval casualties (from 21 to 37 years of age) with from 12 to 20 per cent body surface burns who recovered. Histologically interstitial myocarditis with perivascular infiltration of leucocytes was observed in the rabbits. Buss and Hartman reported 2 cases in human beings (among 6 autopsies) of microscopic fragmentation of the myocardial muscle fibers.

M. Pathology of the central nervous system.

Delirium, stupor, coma, convulsions, hyperpyrexia, and Cheyne-Stokes respiration signs which may indicate central nervous system injury have been described following extensive burns. There have been very meager reports on the pathological changes of the nervous system. Wilson in reporting on a series of extensive scalds and burns mentioned toxic damage in the brain in occasional cases but did not localize the lesions. Pack quoted Cnle as saying that the central nervous system injury was seen only as a result of profound shock. Mallory and Brickley reported cortical ganglion necrosis in 1 of the Coconut Grove cases, but the patient had suffered from severe anoxia in addition to external burn. She had evidence of carbon monoxide poisoning, shock, and severe respiratory injury the first two causing anoxia from the start and the latter causing it later.

Walker and Shenkin have reported on 6 patients who were observed to die of sudden respiratory arrest. All their patients showed essentially the same signs clinically: disorientation and mania or stupor with abrupt failure of respiration but without obstruction of the airway. Five of the patients died about the fourth day but the sixth died on the sixty-second day. Post mortem examination showed cerebral edema with evidence of marked increased intracranial pressure including widening of the gyri, narrowing of the sulci, herniation of the temporal uncus through the incisura of the tentorium and herniation of the cerebellar tonsils into the foramen

magnum. There were marked changes in the smaller blood vessels consisting of degenerative changes of the endothelial lining with occasional breaks and perivascular petechial extravasations. The ganglion cells throughout the brain showed toxic degeneration, but the most striking changes were in the cortex and hypothalamus particularly in the latter.

According to these authors the pathogenesis of these lesions is not clear. Anoxia or the presence of a circulating toxin (32) as suggested by Christophle must be considered. He showed by cross circulation experiments that changes occurred in the paratubular centers especially at the paraventricular and supraoptic regions of the anterior thalamus. It should be borne in mind however, that Walker and Shenkin's patients showed generalized edema as well as cerebral edema, and it is possible that the cerebral changes are a secondary effect. Many additional studies are needed to clarify these points. Unfortunately the few autopsies that have been done on burned patients have seldom included an examination of the head.

METABOLIC CHANGES IN BURNS

A. Electrolyte metabolism

The findings of a decrease in plasma chloride concentration in the first few days following an extensive burn first reported by Davidson in 1926 has since been confirmed by a number of workers (32, 180, 163, 179, 70, 44, 177). These later studies have also demonstrated a decrease in serum sodium concentration and a decrease in urinary sodium and chloride excretions. Fox and Keaton Cope (44) and Hirsfield (95), using radioactive sodium have confirmed Underhill's and Lowdon's findings that much of the lost sodium chloride went into the burned area.

A shift of some sodium into the injured cells in the burned area with a shift from the injured cells of an equivalent amount of potassium has been demonstrated by Fox and Keaton and Tabor and his associates (170). The actual rise in circulating plasma potassium concentration is small and well below the toxic range for normal animals (196). However, Tabor (171) has shown that the shocked animal is considerably more sensitive to rises in plasma potassium concentration than the normal animal.

B. Nitrogen metabolism

Cuthbertson first noticed in 1930 that patients with fractures excreted abnormally large amounts of nitrogen in the urine for weeks after the injury and that this was associated with a loss of weight

and muscle wasting. Lucklo noted a similar process in a burned patient. His observations were amplified on large numbers of patients in a group at the Boston City Hospital (114) during the last 3 years. It was found that all severe burns that were neither anuric nor too severely oliguric had a high output of nitrogen in the urine during the first 3 weeks and that in a few cases this output continued for many months. Steady losses of from 25 to 30 grams of nitrogen per day have been observed frequently, and on an occasional day the loss may be as high as 45 grams. This early increase in urinary nitrogen excretion has also been reported following any acute trauma, poisoning or infection (25, 50, 99, 124). The cause of the excessive nitrogen excretion has not been finally determined. There may be more than one precipitating factor. Associated with the high urine excretion is an early high nonprotein nitrogen level in the blood which is the result not only of a decrease in kidney function (transient or permanent) but also of an increased production of nonprotein nitrogen products (76). Clearing of the increased nonprotein nitrogen is counted for only a small fraction of the total urinary nitrogen in urine. In severely burned patients there is destruction of large amounts of tissue followed by autolysis and absorption of its products. There is also the possibility that the protein catabolism is increased by the absorption of specific substances from the burned areas (139) and from the so-called "toxic degeneration of protein" associated with fever and infection (140). Increased glucocorticosteroids may be responsible for part of the increased protein breakdown. Browne postulates an increased production of S hormone by the adrenal cortex and simultaneously a decreased production of A hormone which results in an increased protein breakdown as a step in the formation of glucose. In any event it has been recently shown that marked abnormalities of the carbohydrate metabolism do occur in severely burned animals (141) and human beings (176) and are associated with hyperglycemia, lactic acidemia and a lowered carbon dioxide combining power. This will be considered in more detail later.

Harker et al. (91) found a rise in plasma amino nitrogen, a slight rise in plasma ammonia nitrogen and a variable nitrogen but no change in liver ammonia nitrogen or amide nitrogen. Taylor et al. (101) showed that plasma amino acids in human beings and found rises only in patients with severe burns who were in shock. Taylor et al. (101) also found that the plasma amino acids in the urine of these patients were in shock. Taylor et al. (101) also found that the plasma amino acids in the urine of these patients were in shock.

early increased nitrogen, both in the blood and urine is due in some cases to the presence of normal amounts of "residual nitrogen," in addition to an increase of normal substances such as urea, creatine, creatinine and amino acids, which are found in the normal blood and urine. Satisfactory chemical characterization of the compounds has not been made.

At the same time that from 25 to 30 grams of nitrogen are being excreted in the urine an additional 30 to 40 grams of nitrogen may be lost in the surface of the burn daily (173, 95, 47). So important losses of nitrogen from the surface are commonly seen only in extensive deep burns. In these the losses may continue over long periods of time. Early after superficial burns there is a large outpouring of plasma-like fluid through the skin. This contains a high proportion of protein. Later during the sloughing and granulating stages of deeper burns there is a steady and considerable loss of protein in the form of purulent material from the surface. The amount of loss varies directly with the area involved. These losses continue until healing is complete. Such losses from surfaces and wounds have not in the past been considered in calculating conventional nitrogen balances, and it must be realized that errors of great magnitude may be introduced in such studies unless this factor is considered.

While the large quantities of nitrogen are lost in the urine and in the drainage from the wounds of such patients, the protein intake is likely to be greatly reduced by reason of pain, anorexia and poor gastrointestinal function. The negative nitrogen balance occurring under these conditions may have serious effects in a few days in the patient with already depleted body protein and in a few weeks in a patient with excellent protein nutrition. This is reflected in the development of a progressive hypoproteinemia. This is an extremely serious metabolic sign. During the first week following a burn a transitory hypoproteinemia may be present. It is due to shift of water, electrolyte and protein from the blood stream into the subcutaneous tissue and edema. This early hypoproteinemia is without nutritional significance. On the other hand, a continuing fall in plasma proteins after the first week is a good marked tissue protein deprivation. Laboratory studies are taken early, weight loss, edema, loss of strength, and death from malnutrition ensue. Methods to combat this process will be discussed.

C. Carbohydrate metabolism.

Hyperglycemia, lactic acidemia and a lowered carbon dioxide combining power are frequent accompaniments of severe burns.

in human beings and animals following burns (54, 180, 127). The extent and duration of the changes in these blood constituents are roughly proportional to the severity of the burn. Clark and Rossiter working with rats and Greenwald and Eliasberg (79) working with rabbits found decreases in the muscle glycogen following burns. Similar determinations have not been made in human beings. Any increase in lactic acid production due to an increase in the rate of muscle glycogenolysis may result in hyperglycemia through conversion of the lactic acid to glycogen and glucose in the liver. The rate of lactic acid formation following burns is, however, apparently greater than the liver can handle, resulting in lactic acidemia as well as hyperglycemia. In addition to an increased glycogenolysis, another possible source of the extra blood sugar is glucose derived from protein (24).

Many investigators have emphasized the role of the adrenal glands in the production of abnormalities in the carbohydrate metabolism in burns. Hartman (94) has demonstrated an early increased adrenalin production. Browne and Cope *et al.* (47) found increased 17 ketosteroid excretion in the first few days following burns, which was followed by a decrease below normal values. Numerous pathological studies, as already mentioned, have revealed adrenocortical hypertrophy and marked depletion of lipoids. Adrenalectomy was found by Slocum and Lightbody to prevent the lactic acidemia but not the hyperglycemia in burned rabbits, while Clark and Rossiter found that neither the lactic acidemia nor the hyperglycemia was abolished. It appears that although the adrenal glands may play an important role in the production of abnormalities in carbohydrate metabolism following burns, the entire picture cannot be explained on this basis and indeed the effect of the adrenal glands may be of a secondary nature.

D. Vitamins

Increased demands for vitamins in burns have been suspected for some time by analogy with studies showing increased needs for vitamins in other diseases (81). Empirically vitamin preparations such as cod liver oil have been used locally (121) and orally for many years in the treatment of burns. Very few assays of vitamins in the blood, urine, or tissues to determine the actual requirements in burns have been made.

In 1937 Usbekov studied the content of ascorbic acid in the adrenal glands and in the liver of guinea pigs that were kept on various diets before and after burning. He found a progressive

fall in the ascorbic acid level in these organs following burns of from 45 to 50 square centimeters of skin. This decrease occurred in all animals no matter whether their diets were high or low in ascorbic acid. The pigs on partially deficient diets showed indolent healing and 'poor' granulation tissue and lost much weight. The animals on better diets lost less weight and had 'better' granulation.

Lam reported low plasma ascorbic acid concentrations in a few patients with extensive burns. Clark and Rossiter and Harkins (90) reported a decrease in adrenocortical ascorbic acid concentration following burns in rabbits, rats, and guinea pigs. Lund, Taylor, Johnson, and associates have studied plasma ascorbic acid concentrations and urinary excretions of ascorbic acid, thiamin, riboflavin, and *N*-methyl nicotinamide in man in the acute and chronic stages of burns. They have found that in patients with severe burns on high protein diets supplemented with two or three times the National Research Council daily allowances of these vitamins recommended for healthy individuals (38) the plasma level of ascorbic acid and the urinary excretions of all four vitamins may decrease to very small quantities. Even with small burns the patient on a nonsupplemented house diet may do the same thing. In patients with consistently low plasma and urine ascorbic acid levels the granulation tissue is absent or edematous, skin grafts fail and epithelialization is delayed. Burned patients with low excretions of B vitamins may have poor appetites, poor bowel function, asthenia and poor morale. The extra needs for vitamins commence with the burn and remain until healing is complete. In general the extra amounts needed to prevent depletion parallel the area of unhealed burn. Whether it is desirable to try to maintain fully saturated levels of ascorbic acid in the blood and the excretion of appreciable quantities of all four vitamins in the urine is not known. The maintenance of such levels will, in very severe cases, entail the administration of up to 2.0 grams of ascorbic acid, 50 milligrams of thiamin, 50 milligrams of riboflavin, and 500 milligrams of niacinamide. Comparable studies on any of the fat soluble vitamins and on all other water soluble vitamins have not been made.¹

BURN SHOCK

Burn shock may be defined as a condition of low blood plasma volume, low cardiac output, low blood pressure and increased peripheral re-

¹Since this was written Andrews and associates have reported studies of the balance of riboflavin in burns and have found an increased need for it during convalescence.

LUND GREEN TAYLOR LEVENSON BURNS

Chart 1 Hematological changes in patient with burn of face and hands and without shock.

degrees C. for from 2 to 3 minutes died in shock without visible edema and exhibited insufficient local fluid loss to account for death. Similar results were obtained when larger areas of the body were severely burned for 10 seconds. These authors concluded, It is therefore apparent that there are at least two mechanisms capable of producing shock one due to local fluid loss and the other due to some unknown factor.

Another important contribution to our knowledge concerning toxins has been made by Perlman, Glenn and Kaufman who described a large amount of a new globulin fraction in the lymph collected directly from the burned area in calves. This globulin may represent a toxin.

Rawlinson and Kellaway have found great increases in phosphatase phosphate proteolytic

enzymes esterase, and catalase from heated liver slices as the temperature approached 50 degrees C. Kellaway and Rawlinson studied tissue in jury by heat in isolated limb preparations. From the perfused hind limbs of guinea pigs and the forelimbs of cats histamine was liberated between 45 degrees and 50 degrees C. In the early hours of perfusion a substance relaxing smooth muscle which inhibited the stimulating effect of histamine was present in the perfusate. No active adeny compounds could be detected between 37.5 degrees and 50 degrees C. but cardio-depressant activity was found between 42 degrees and 50 degrees C. This was also present in the subcutaneous edema. It was heat stable and was not diminished by incubation with cat muscle or cat liver extracts. The hydrogen ion concentra-

tion of the perfusate showed its greatest increase between 44 degrees and 45 degrees C. The small output of inorganic phosphates between 37.5 degrees to 41 degrees C. was markedly increased at the higher temperatures. Alkaline phosphatase, lipase, and proteolytic enzymes were also set free above 41 degrees C. These authors concluded

"The demonstration that lipase and proteolytic enzymes were set free from the perfused hind limb of the cat above 41 degrees C. gives color to the possibility that toxic products may be formed by enzymatic activity in the tissue spaces. Proteolytic enzymes in lymph from the burned area have also been reported by Zamecnik *et al*

Rose and Browne have found very high blood histamine levels immediately after the burn. The amount of histamine present decreases rapidly as toxemia develops. These findings are not altered by the administration of sufficient plasma to prevent hemoconcentration. There is a correlation between the degree of injury and the decrease of the histamine content of the blood. Thus, the most marked decrease has been noted from 12 to 36 hours before death. Similar findings have been observed in cases of fatal shock.

Beloff and Peters have found a proteinase that is liberated from burned skin that they discuss in relation to "burn toxin theories," but they do not claim that it causes burn shock.

Muys and Hardenbergh have observed that the oxygen consumption of normal rat liver slices is increased when measured in lymph from the burned legs of calves or one dog as medium. The increase over similar measurements in normal lymph was as great as 41 per cent. When serum was collected after burning a smaller increase was found. In this connection Taylor and his associates (196) have found an increase in the basal metabolic rate in severely burned patients. The rise was greater than could be accounted for by the fever that was present at the time of the test.

Aub (7) has found that the fluid obtained from within the sheath of a muscle that has been made ischemic by the interruption of its circulation produces shock when injected into normal dogs. Exotoxins produced by organisms of the bacillus welchii group were found in this fluid. These bacilli were found to be normal inhabitants of normal dog muscle. Under the anaerobic conditions of these experiments the number of organisms and the amount of toxins produced are greatly increased. The toxic effect of this fluid is nullified if suitable antitoxin is mixed with the fluid, or injected separately but simultaneously into the dog. Animals immunized with toxoids are resistant.

Chalkoff and his associates have found that fluid expressed from the skin and subcutaneous tissue of burned areas in dogs is toxic to rats. Gram positive anaerobic bacilli and other organisms have been identified in this fluid. After Zeitz filtration the fluid is still toxic in most instances. Aub has found that these anaerobic organisms are not normally present in the tissues of man. At present there is no evidence that these toxins are important in the pathogenesis of burn shock in man.

This discussion of burn toxins in relation to burn shock is far from complete and mentions only a few of the important studies that have been made. There seems to be no doubt that many chemicals are released from the area of a burn that all together play a part in the depression of the circulatory system after a burn.

3. Pain. At the moment of burning and for a few minutes after burns cause sharp pain. Then there follows during the next few hours and, even occasionally for several days, a period of almost complete freedom from pain. At later stages burns may be among the most painful of all diseases. Until recently pain has been considered to be a very important cause of shock following burns. Many experiments have been carried out to evaluate the importance of pain as a factor in various other forms of shock, but in burn shock the only experiments of this kind are those of Kabat and Hedin. Unfortunately their experiments on dogs are inconclusive for several reasons, particularly because their burns did not produce shock but merely produced a moderate rise in the hematocrit. Recently the experimental evidence from studies of afferent stimuli as a factor in the production of traumatic shock has indicated a much smaller influence from such stimuli than the many older studies, such as those of Crile, indicated. From an excellent recent study of traumatic shock in dogs Phemister and Laestler conclude, in part, as follows "No evidence was obtained from these limb trauma experiments that a flow of nociceptive stimuli from the injured field is an important contributing factor in the initiation of any circulatory impairment or shock which followed."

Evidence derived from the treatment of patients with burns in shock shows that, even in the exceptional instances with severe pain, sedatives have essentially no therapeutic effect on shock comparable to the effects obtained with suitable intravenous fluids such as will be described.

4. Cold and heat. Under war conditions and in connection with civilian airplane accidents some patients with burns suffer from exposure to

cold or heat for long periods of time before and after an accident. In peace time civilian life such complications are only seen in disasters of the living magnitude or in the case of individuals living under isolated conditions. Either excessive cold or excessive heat will contribute to the severity of shock, but quantitative studies of the role played by cold and heat have not been made. Some very important observations on the treatment of burn shock in a chilled or heated environment will be considered in the section on the treatment of shock.

B The diagnosis of burn shock

Many writers have described the clinical picture of burn shock. As with other forms of shock it is very simple to make the diagnosis in its final stages. One merely has to determine that the pulse and blood pressure are unobtainable. However the earlier periods of impending or mild shock are more difficult to diagnose. Since shock once it is well established is much more difficult to treat than when it is in its earlier stages, it is important to foresee impending shock so that prophylactic measures can be taken.

Careful estimation of the area and of the approximate depth of a burn is important for the anticipation of shock. As already mentioned any patient with a burn area of 25 per cent or greater will probably suffer from shock and any patient with a burn area of 25 per cent will probably suffer from fatal shock unless prompt and active treatment is given.

The pulse and blood pressure should be taken at one-half hour intervals during the first 24 hours. However they are not good indicators of impending shock, since because of the increased peripheral resistance the pulse may remain slow and the blood pressure normal when the blood volume has already been reduced to a critically low level. Suddenly the blood pressure will fall to a dangerous level and even then the pulse may not rise.

Direct blood volume determinations are the best indications of reduced blood volume but they are not practical for clinical work. Hematological determinations are practical and serve as essential guides. Hematocrit, hemoglobin and red blood cell determinations are useful. Except for research purposes serial determinations at 2 to 3 hour intervals of any one of these is sufficient. The blood examined must be venous rather than capillary blood because of stagnation in the capillaries.

As indicated in Table II apparently normal hematological findings may be seen in the pres-

TABLE II—CALCULATED CHANGES IN BLOOD AND PLASMA VOLUMES ACCORDING TO CHANGES OF THE RED BLOOD COUNT PER CENT OF HEMOGLOBIN AND PER CENT OF PACKED RED BLOOD CELLS IN PATIENTS WITH VARYING DEGREES OF ANEMIA BEFORE INJURY

	Observed				Calculated

190	190	9.5	66.5	33.5	10	10
200	200	10	70	30	0	0

ence of severe loss of plasma in a previously anemic patient. Note in Table II that a slightly elevated hemoglobin of 110 per cent, if found in a patient whose preburn hemoglobin was 70 per cent, indicates that he has already lost 33 per cent of his plasma volume and 37 per cent of his blood volume—a loss that would probably cause severe shock.

Serial plasma protein determinations also provide useful information. As plasma is lost from the vascular bed there is a shift of low protein extravascular (chiefly interstitial) fluid into the blood stream. This results in dilution of the plasma protein. If the shift is rapid there is a greater fall in the plasma protein concentration than in the hemoglobin concentration. In some instances the hemoglobin may remain normal and a falling plasma protein may be the chief laboratory indication of impending shock.

Accurate records of urine output must be kept. Lauson *et al.* have shown that renal blood flow and urine output may be markedly reduced at a time when the peripheral pulse and blood pressure are normal. If the urine output is good one may feel sure that the general circulation is good; if however the output falls one must anticipate early failure of the general circulation.

C Secondary effects of burn shock

The effects of severe burns without shock and of severe shock without burns are similar in many instances. For instance, increases in the blood sugar, lactic acid, nonprotein nitrogen, amino acids, ammonia, and hydrogen ion concentration and decreases in sodium chloride and ascorbic acid are common to both. When shock occurs in burns it results in an intensification of the same changes that had already commenced before the shock had started. Quantitatively the severity of these metabolic changes parallels the severity and duration of the shock. One metabolic change, however has been recently observed in shock of various types, including burn shock, that is never seen in burns, no matter how severe, if shock is prevented by efficient treatment. Tagnon and his associates (174) have demonstrated the occurrence of fibrinolysis in both burn and hemorrhagic shock. Fibrinolysis is the spontaneous dissolution *in vitro* of the clots in blood within 24 hours. This phenomenon disappears promptly with recovery from shock.

Another complication of burn (and other forms of) shock is "irreversible shock." As a result of the anoxia and cellular injury that results from prolonged circulatory insufficiency a point is reached where complete restoration of the blood volume will no longer result in the return of a sufficiently adequate circulation to maintain life. If the systolic blood pressure remains below 90 mm. for more than 3 or 4 hours the shock is almost surely irreversible, and frequently it may become so in a shorter period of time. Studies have not been made on "irreversible burn shock," but studies (66) on "irreversible hemorrhagic shock" have indicated that failure of liver function is one of the earliest and most important changes that lead to "irreversibility." There has been discussion in the past of the role of generalized capillary leakage as a factor in the initiation of "irreversible shock." Some observers have claimed that it was important, and others that it did not occur. Fine and Selligman (67) have demonstrated why both sets of observers may have been correct in their observations under the limitations of their particular experiments. They have shown that there is no capillary leakage at a distance from the burn or other trauma, or at any place, when hemorrhagic shock is studied, from the commencement of shock or during the whole time that the blood pressure is very low. However if the shock period has been long enough, generalized capillary leakage starts as soon as the blood pressure is brought up by restoration of the blood volume. This leakage under these condi-

tions may be one of the major factors in determining "irreversibility." Because of the great danger of "irreversibility" it is imperative to prevent shock when possible and to treat it promptly and vigorously when it occurs.

D The prevention and treatment of burn shock.

The first principle of treatment of any form of shock is to avoid, in so far as possible, any treatment of the patient that will increase the shock, and to postpone necessary shocking procedures (such as dressings) until shock has been prevented or treated. The positive measures for the treatment of shock are taken up first. Of these measures, those that restore and maintain the blood volume are of paramount importance and are discussed first. Omission of them can in no way be compensated for by any of the adjuvant methods of treatment discussed later.

1. Human plasma and serum. In burns, as indicated previously, the fluid that is lost from the vascular bed is similar in composition to blood plasma. Consequently it is logical to replace the lost fluid with plasma, and it has been demonstrated that burn shock may be prevented or successfully treated in nearly all cases if seen early by plasma transfusions in adequate amounts.

The amount and rate of plasma administration depends on many factors. First, it should be borne in mind that the amount of fluid lost is roughly proportional to the area of surface burn. However burns of certain areas, such as the face and genitalia, which are highly vascular and have loose subcutaneous tissue are accompanied by particularly high fluid losses. Second, the rate of fluid loss is maximal in the first few hours after a burn and then gradually decreases so that at the end of from 36 to 48 hours an equilibrium is reached between the amount of fluid lost and the amount returned to the blood stream from the interstitial spaces. Third, both clinical and laboratory data must be considered in determining the amount of plasma to be given.

Progressive hemoconcentration, falling plasma protein concentration, falling blood pressure, and a rising pulse are indications of impending shock. There are many formulas suggested for estimating the plasma dosage based on blood concentration (50, 58). The most commonly used is that of Harkins (89). (a) give 100 cubic centimeters of plasma for every point that the hematocrit exceeds the normal of 45 per cent, or (b) give 50 cubic centimeters of plasma for every point that the hemoglobin exceeds the normal of 100 per cent.

As pointed out previously, such calculations, based on an assumed normal hematocrit may be

Chart 2. Effect of plasma on burn shock. Blood pressure was not obtainable. (The vertical arrows mean that the blood pressure is not obtainable.)

erroneous if the patient is anemic prior to injury. Serial hematocrits should suggest this possibility and calculations should be based on an approximate preburn hematocrit. In addition, such calculations do not indicate the amount of plasma that will be needed to manage the entire course of the burn shock. Consequently frequent hematological observations must be made during the first 24 to 48 hours. This is well illustrated in Chart 2.

The patient whose course is outlined in Chart 2 was a man of 50 with flame burns of 55 per cent of his body surface, chiefly deep. His blood pressure, pulse, hematocrit, and hemoglobin were normal on entry. Ten units (2,500 c. c.) of plasma were given in the first 7 hours during which time his burns were treated with tannic acid and silver nitrate. His hemoglobin pulse and blood pressure remained normal, and plasma infusion was stopped. Five hours later his hematocrit and hemoglobin were markedly elevated but his pulse and blood pressure were still normal. During the next 2 hours the patient became chilly, nauseated and complained of feeling sick. Sud-

denly he became cold, pale and clammy. His pulse was very rapid and thready and his blood pressure was unobtainable. The administration of 1,000 cubic centimeters of plasma during the next 90 minutes restored the hematocrit to normal, but had no effect on the pulse and blood pressure. In the next 10 minutes 800 cubic centimeters of plasma were given into the femoral vein by the multiple syringe technique with a return of the pulse and blood pressure to normal.

This illustrates the necessity of administering plasma rapidly when shock is present. Advantage of rapid infusion in shock is also implied in the recent publication of Kohlstaedt and Page who advised intra-arterial rather than intravenous administration of fluid. However one may construe the efficiency of their intra-arterial administration of plasma to a more rapid administration. Caution must be used of course, in infants, old people, and those with heart disease. In the normal adult with a large burn as much as 2,000 cubic centimeters may be given in a period of an hour without danger of overloading the circulation.

The dosage of plasma on the basis of the extent and location of the burn is also of value, particularly where laboratory facilities are not available. About 100 cubic centimeters of plasma for each per cent of body surface burned should be administered to patients with 10 per cent or more area burn. All of this plasma should not be given at once but should be given according to the following schedule which approximates the rate of fluid loss: one-half should be given in the first 4 to 6 hours, one-quarter in the next 6 hours, and the last quarter in the next 12 hours. Smaller amounts may be required in the next 24 hours in rare instances.

Attention should be paid to the clinical appearance of the patient. One of the best guides of adequate therapy of shock is a good urinary output. If a clinical impression of additional plasma need is at variance with the laboratory findings, the latter should be disregarded. The first 6 hours following a severe burn are critical ones so far as plasma administration is concerned. It is during these first few hours that the physician has the greatest opportunity to prevent shock. No unnecessary delays should be tolerated. When the usual peripheral veins are not available, there should be no hesitation about employing the femoral route or in cutting down on a vein. The use of the femoral route was a lifesaving measure in the treatment of many patients at the Boston City Hospital where at least a thousand of such punctures have been made for withdrawing blood or injecting various solutions intravenously.

Another factor influencing the amount of plasma required is debridement. It is common experience that large amounts of fluid are lost from the body during such procedures as debridement and the cleansing of large burns. The burned skin, although badly damaged and partially permeable to plasma, nevertheless acts as an important dam to the extravasation of fluid because of the coagulation of exudates and partial drying of them on the surface. The removal of this barrier and consequent opening of tissue spaces is accompanied by an increased fluid loss.

This may be seen by examination of Chart 3. The patient whose course is described in Chart 3 was a 32 year old woman with flame burns of 65 per cent of her body surface, chiefly deep who was treated initially with 7 units (1750 c.c.) of plasma given over a period of 1½ hours. At this time she went into shock despite the absence of significant hemoconcentration. It was known that her hemoglobin prior to injury was about 85 per cent. After a further period of 2 hours, during which time she continued to be in shock,

infusion of plasma was recommenced and the patient responded with a rise of blood pressure to normal. While the infusion was still being administered, debridement was begun. During the course of the operative procedure both the hematocrit and hemoglobin rose abruptly which indicated a considerable increase in the rate of fluid loss. Wilson *et al.* who used cleansing and debridement routinely prior to tanning, commented on such fluid loss and pointed out the high incidence of shock following this procedure.

Serum may be used in place of plasma with equally good results, as has been demonstrated by its use in large series of cases in Canada and Great Britain. The reactions which were reported in the early days of serum have not been seen in the later series of cases. Most of the early reactions may have been due to the fact that fresh serum contains thrombin and other substances which are toxic. After a few hours, and certainly after the 2 weeks during which the serum is now held before use, such substances have disappeared.

Human albumin. As a result of the work of Cohn and his associates, the United States Navy and the American Red Cross have produced large amounts of human albumin for the treatment of shock. Very little has been available for civilian use to date. A few reports indicate that it has value in the treatment of burn shock (10). At present it is shipped in highly concentrated form (35%) and can, if indicated, be administered without dilution. For emergency treatment of the patient who is not dehydrated it may well prove to have some definite advantages over plasma. It has the advantage that it has a much greater osmotic effect on the circulation than the same amount of protein in the form of plasma. However it has the disadvantage of being a "pure solution" that is, it does not contain substances such as prothrombin which are also lost or depleted in shock (174). Zamcnik (198) has shown that in dogs with hemorrhagic shock which are treated with albumin there is a marked fall in the prothrombin concentration, whereas no such fall occurs if whole blood or plasma are used. Janeway and associates have reported a marked fall in the plasma globulin in a burn patient who received large quantities of albumin intravenously. Additional saline solution and water must be given to patients receiving albumin to replace the interstitial fluid which is drawn into the vascular system by the osmotic action of the albumin.

3. Electrolyte. Saline solution has long been used in the treatment of shock. There is evidence that if it is given intravenously at rapid or moderate rates of injection the blood pressure of the

Chart 3. Effect of débridement on rate of fluid loss in a patient with an extensive burn.

shocked individual may be raised but the effect is frequently transient. In addition it appears that plasma protein may be "washed out" by the saline solution (21). For these reasons saline solution was replaced by plasma or serum in most clinics when these solutions became available, as they did quite generally in the United States, Great Britain, and Canada between 1940 and 1942. Interest in the use of saline solution alone or in conjunction with other sodium salts has recently again been aroused by the reports of Rosenthal and of Fox. Rosenthal experimenting on mice with standardized burns, has shown that the effects of sodium salts given intraperitoneally or by mouth very soon after the burn are slightly but significantly superior to the effects of serum given intravenously in preventing death of the animals within 48 hours. In his series the effect of the serum appeared to be due not to the contained protein, but to the sodium. He also showed that the therapeutic effect of the sodium salt was due

to the sodium radical rather than the acid radical since different sodium salts acted in the same manner. Potassium salts increased the mortality. Saline solution when given intravenously was not as effective as when given by mouth. Isotonic saline solution was more effective than the hypertonic solution. Prinzmetal *et al* have also reported good results in mice with sodium therapy. Fox treated a number of severely burned patients by the oral administration of sodium lactate or sodium bicarbonate and saline solution. He gave from 10 to 15 per cent of the body weight of isotonic sodium salts in the first 24 hours. Any vomiting such as occurs frequently in patients with severe burns, was treated by the administration of more oral fluid. The results appeared to be good. It must be stressed that in the studies reported the sodium was used chiefly for prophylaxis and not for treatment of fully developed shock. In addition dangerously low plasma protein levels were seen in some of the patients

This work needs careful consideration. For the moment it would appear that while it is true that there is a deficit of sodium in the burned patient, it is also true that there is a deficit of other substances and, although it undoubtedly is necessary to replace the sodium, it is also necessary to replace the other substances. It appears to us that sodium salts are necessary adjuncts to the treatment of burn shock, not the sole therapeutic agents. The work of Moyer *et al* and Abbott *et al* on the use of sodium chloride and sodium bicarbonate solutions with whole blood which will be described in the section on whole blood, are of interest in this regard.

4. Whole blood. Whole blood was used extensively to treat burn shock until 1940. Then plasma and serum became generally available in large quantities and almost entirely replaced it. Among other reasons it was widely believed that additional red blood cells could serve no useful purpose when the blood was already concentrated. However during the last 3 years, interest in whole blood has revived, principally because of the work of Moyer *et al*. They studied the therapeutic effects of various solutions on the shock of severe, deep burns of dogs. The dogs were shaved and two-thirds of their surface areas were scalded for 30 seconds by water at 85° C. A combination of transfusions of defibrinated blood and gavage of normal saline solution with added sodium bicarbonate solution was the only form of treatment that prevented shock without inducing such complications as cerebral and pulmonary edema in compatible with life. The unsuccessful forms of treatment were (1) intravenous administration of saline and bicarbonate solutions, (2) intravenous administration of saline and bicarbonate solutions and dog's serum, (3) intravenous administration of dog's serum with saline and bicarbonate solution by gavage and (4) intravenous administration of defibrinated blood with water given orally ad libitum. Abbott and his associates have found that whole blood transfusions given during the first day of the burn not only aid in preventing shock in human beings, but also alleviate or prevent the subsequent anemia that frequently appears about the third day after plasma has been used. Levenson *et al* (115) and Evans and Bigger have also treated burn shock successfully with whole blood in a small series of carefully studied patients.

5 Glucose. The early increased blood sugar in severe burns might be considered to contraindicate the administration of glucose intravenously. However Taylor and associates (176) have demonstrated that there is no impairment of

glucose tolerance or loss of excessive amounts of glucose in the urine under these conditions. In addition burns cause depletion of the muscle glycogen and possibly of the liver glycogen so that efforts should be made to restore glycogen to these tissues by an adequate administration of carbohydrate. Finally as mentioned previously there is an early increase in the nitrogen catabolism, and glucose in large amount may alleviate this. Glucose should be given in substantial quantities. Harkins *et al* (91) recommended up to 300 grams in the first 24 hours for severe burns. However glucose must be considered to play only a minor role among the many substances given to these patients, and to be almost or entirely without value if it is given in pure solution for either prevention or treatment of shock.

6 Gelatin. Degraded solutions of gelatin have been studied as plasma substitutes in the therapy of burn shock in dogs (147) and the consensus of opinion is that properly prepared gelatin solutions are as effective in the acute phase from the points of view of osmotic properties and mortality as plasma. Koop (108) has come to the same conclusion in working with human patients. However plasma possesses a number of properties beyond the osmotic characteristics shared by gelatin and since there are other losses from the blood beyond the loss of osmotic properties it would appear that plasma would offer some advantages.

7 Gum acacia solution. Although interest in this solution was shown by several investigators up to 1940 its use has completely stopped with the advent of human plasma and serum. Not only have these substances been found to be better but, also acacia has been found to be harmful when given in repeated doses (8a).

8 Oxygen. The defenses of the body against shock and the efforts to maintain blood volume are all in reality attempts to achieve one goal, the maintenance of normal cellular metabolism which is dependent upon adequate oxygenation of the tissues. As indicated previously tissue anoxia results from the failure of the peripheral circulation. There is no experimental evidence that inhalation of 100 per cent oxygen alleviates the tissue anoxia accompanying shock. Oxygen has been widely used clinically in the treatment of burn shock, but the only clear indication for it is complication of the burn shock by respiratory tract injury.

9 Position. The indications for raising the foot of the bed or placing the patient in the Trendelenburg position are not as clear in the treatment of shock from thermal burns as in the

reatment of simple syncope, since in the burned patient there is no pooling of blood comparable to that in simple syncope. In the burned patient the fluid is lost externally or into the subcutaneous tissue, and it cannot be readily returned to the vascular tree by change in position. However it appears that the circulation to the brain is improved by tilting the bed even though the blood volume may not be materially altered. It is especially important to raise the foot of the bed during the first few minutes after the onset of shock while other more effective methods of treatment are being started.

10. External temperature. Because many patients in shock are cold it has been customary to cover them with many blankets and also to use hot water bottles or other sources of heat. Blalock has shown that overheating is detrimental to the animal in traumatic shock, and Elman and associates (61) have shown that both heating and cooling are harmful to burned animals. As already mentioned, occasional patients have markedly high fevers from 18 to 24 hours after a burn. It is important that for patients in shock with a rectal temperature below 34.0 degrees C. or above 40.0 degrees C. very active measures be taken to warm or cool them promptly but these measures must be stopped as the temperature approaches normal.

11. Sedation in shock. As recently as 1942 it was customary to treat burns with very large doses of opiates. Beecher has shown that this is not a safe procedure when shock is present. He points out that morphine is contraindicated in the treatment of fear or hysteria or of any condition in the presence of anoxia. It should be given only to relieve pain. Most importantly he calls attention to the fact that no drug is readily absorbed from the tissues if administered subcutaneously or intramuscularly to a patient in shock. He presents the history of a patient in burn shock who was given repeated doses of morphine subcutaneously without effect. As soon as her circulation was effectively restored by treatment with plasma the whole amount of the drug was taken rapidly into the blood stream and gave the usual effects of an overdose of morphine. Energetic measures were needed to combat these effects. Therefore when opiates are indicated in patients with shock they must be given intravenously.

Another aspect of this problem has been studied by Elman (61) who showed that the mortality of burned dogs was increased when usual doses of morphine or of barbiturates were given. In view of these findings, morphine and other sedatives

should be used cautiously in patients with incipient or actual burn shock. Anesthetics have the same harmful effects, and are very dangerous in incipient or actual burn shock. Cyclopropane is safest if one is necessary (21) but Levenson and his associates have found no occasion to use anesthesia at the time of the first dressing in their most recent 500 cases seen during the last 2 years.

12. Pressor drugs. Frank and his associates have recently studied the therapeutic effects of various pressor drugs in irreversible hemorrhagic shock in dogs. They found no indication of beneficial results from the use of pitressin with or without ergotamine, paredrine, coramine, or tuamine. Earlier work by Cannon (30) indicated that the capillary blood flow may be actually lowered when such drugs are used. No such studies have been made on burn shock, but by analogy these studies indicate that these drugs would be of no value.

13. Adrenocortical extract. As described in the section on pathology there is evidence of adrenal injury following burns. In addition there is laboratory evidence of increased outputs of adrenalin (159) and of various corticosteroids (24, 47). Rhoads, Wolff and Lee (157) reported promising results from the use of adrenocortical extract in the treatment of burn shock. A more recent report by the same authors reverses this opinion (158). The later clinical observations were corroborated by the experimental studies of Rosenthal, who found that in standardized burns in mice there is no protective action produced by either desoxycorticosterone or adrenocortical extract injected subcutaneously when compared with controls injected with saline solution. Lowdon *et al* had previously reported failure to decrease the mortality of burned animals by the use of desoxycorticosterone. Cope and Moore (45) have demonstrated in dogs that adrenocortical extract has no influence on the abnormal permeability of the capillaries in the burned area. In view of the failures encountered, there is no indication at present for its use in the early post burn period.

14. Vitamins. Govier working on hemorrhagic shock in dogs, has indicated that B complex vitamins, particularly thiamin have a definite therapeutic effect on the shock. In addition to their findings mentioned previously on the effect of burns on vitamins Lund, Johnson Taylor and associates (126) have found great depletion of water soluble vitamins during the shock phase of burns. They believe it is logical to administer large doses of these vitamins early after admission of the patient.

15 Anesthesia and surface treatment. The very serious effects that these items may have on burn shock will be discussed in the subsequent section on surface treatment.

RESPIRATORY COMPLICATIONS

Injury of the respiratory tract is an important complication of a few thermal burns. It should be suspected in any patient who gives a story of having inhaled large amounts of hot smoke, particularly if consciousness has been lost. Patients with injury of the respiratory tract usually have burns of the face, but this condition may be seen in patients with no external burns (68). Singeing of the fibrillae of the nares, soot on the face, and burns of the nasopharynx are commonly seen in these cases. As described in the section on pathology the fundamental lesion is a necrotizing tracheobronchitis. Finland *et al* found the usual symptoms to be cough, hoarseness, dyspnea, and stridor. The sputum was mucoid, purulent, and bloody. Occasionally casts of trachea and bronchi, resulting from pseudomembrane formation were coughed up. The vital capacity was greatly diminished. Physical examination revealed scattered areas of dullness, hyper resonance, and rales of all varieties, but chiefly crepitant or fine wheezes. X rays showed scattered small areas of emphysema, atelectasis, and congestion. Secondary pneumonia, chiefly due to the staphylococcus aureus, was seen in some patients.

Any patient in whom injury of the respiratory tract is suspected must be watched very closely. A tracheotomy kit should be kept at the patient's bedside. Respirations should be charted every half hour. Examination of the nose, nasopharynx, epiglottis, larynx, and vocal cords should be made. If burns of the nasopharynx are present, swabbing the nose with bland oil and having the patient gargle with a warm soothing solution, such as glucose in water will be helpful.

If cough or dyspnea develops, the air should be humidified. If these symptoms progress in spite of humidification, the patient should be placed in an oxygen tent. Inhalations of 10 per cent carbon dioxide and 90 per cent oxygen should be given for a few minutes every one to two hours to induce deep respirations. The patient should be moved frequently and encouraged to cough. If there is any wheezing or other signs of bronchial spasm, aminophyllin or adrenalin should be given intravenously or adrenalin should be given by nebulizer. Generalized laryngobronchial spasm may occur very suddenly and may lead to death of the patient unless it is relieved immediately. Tracheotomy with artificial respiration may be

necessary. Tracheotomy is also indicated if stridor or air hunger or other signs of laryngeal obstruction appear. Suction through the tracheotomy tube should be done repeatedly as needed. When simple aspiration through the tracheotomy fails, bronchoscopic aspiration may succeed.

A dose of 25,000 units of penicillin should be given intramuscularly on entry and repeated every 3 hours. If the urine output is good, sulfadiazine may also be given. If the patient is restless, one must first rule out anoxia, and, if present, steps such as have been described should be taken to provide for oxygenation. For restlessness due to pain, meperidine hydrochloride should be used rather than morphine or any other respiratory depressant. For restlessness due to nervousness or anxiety the barbiturates should be used (74).

If the patient with injury of the respiratory tract has extensive surface burns in addition, plasma should be given without hesitation to prevent or treat shock. Finland found no evidence to indicate that plasma infusions under such circumstances led to pulmonary edema. Plasma may also very rarely be indicated in the patient with respiratory burns who has no external burns.

INFECTION IN BURNS

Infection is always a serious complication of extensive deep burns, and frequently or rarely according to the efficacy of treatment, a complication of lesser burns. Its control is, therefore, one of the most important aims of therapy.

A. Initial contamination. A burn immediately after the accident harbors few pathogenic organisms since the process of burning sterilizes the skin in the affected area. However unless protected, the lesion is rapidly contaminated. Great sources of serious contamination are the respiratory secretions of individuals handling the patient (33). Also important are the materials which come in contact with the burn and the bacteria that may remain viable in the deep crypts and ducts of the skin in the burned area, or in the skin of adjacent areas.

B. Bacteriology. In careful bacteriological studies of burns in patients cared for in a special ward at the Royal Infirmary at Glasgow Clark (33) found that the hemolytic streptococcus was the predominant infecting organism. This corroborated the previous studies of Aldrich in 1933 at the Johns Hopkins and the Boston City Hospitals. However, most of the studies that have been carried on during the last 4 years at many widely separated civilian hospitals in the United States have shown that hemolytic streptococcal infec-

tions in burns are infrequent (135, 117). They show that burns at all stages are almost always contaminated or infected with several organisms. Aerobic, anaerobic, gram positive, and gram negative bacteria, and cocci may all be found in any single culture. The number of varieties of bacteria found is usually related to the care and variety of the culture methods employed. Serial cultures taken from a single burned area show changes from time to time in the variety and proportions of the different organisms. They also show that the hemolytic staphylococcus is the predominant pathogenic organism. Almost every culture at any stage of the many burns studied by Meloney (135), Lyons, and Levenson (117) have shown it to be present. It has not been eliminated by sulfonamide or penicillin as given to date. Fortunately its mere presence does not prevent successful grafting (117). When the hemolytic streptococcus is predominant, however it does interfere with successful grafting in many cases. Fortunately it may be eliminated by the use of large doses of penicillin (113) or of sulfonamides (3). Acute hemolytic streptococcus infection of the burn with the rash of scarlet fever occurs occasionally in children. It responds well to chemotherapy.

Symbiotic infections in which an anaerobic or microaerophilic streptococcus is associated with one or more other organisms occur rarely (135). Under these conditions there may be burrowing of the infection at the edge of the wound and destruction of otherwise viable dermal tissue.

An unexpected finding of Meloney's study was the frequency with which anaerobic organisms were observed. However there was essentially no clinical infection with the bacillus welchii or other clostridia except the bacillus tetani. It must not be forgotten that clinical tetanus is occasionally seen in burns and that tetanus antitoxin should be given prophylactically to all patients with deep burns.

The more frequently encountered bacteria are listed in Table III in approximate order of their importance.

The skin in dermal burns retains most of the resistance that normal skin has against infection. If rest and avoidance of recontamination are provided, any organisms growing on the surface soon die out as healing progresses (42). With deep burns the problem of infection is much more serious because deep burns are always infected from a few hours after the burn until healing is complete. During the first 2 to 6 weeks necrotic slough is present on the surface and it furnishes an excellent medium for bacterial growth. After the slough

TABLE III—VARIETIES OF BACTERIA FOUND COMMONLY IN CULTURES FROM BURNS

<i>Staphylococcus hemolyticus</i> , coagulase positive
<i>Streptococcus hemolyticus</i> , (beta and gamma)
<i>Bacillus proteus</i>
<i>Bacillus pyocyaneus</i>
<i>Bacillus coli</i>
Diphtheroids
Other staphylococci
Other streptococci
Other enterococci
<i>Pneumococcus</i>
<i>Bacillus mucosus capsulatus</i>
<i>Bacillus welchii</i>
<i>Bacillus tetani</i>
Other clostridia

has separated the open granulating wound continues to harbor bacteria as long as the wound is open. The question of control of infection by local and general measures will be considered later.

HYPERPYREXIA IN BURNS

Patients with burns frequently have a period of high fever (over 41 degrees C) in the first few days after the burn. This is observed in adults only if they are burned extensively but in children, and particularly infants, it may occur as a complication of small area burns. The occurrence of delirium, stupor, convulsions, or coma should suggest the possibility of hyperpyrexia. The oral temperature may frequently be misleadingly low, and rectal temperatures should be taken of all such patients. Infants in particular should have hourly rectal temperatures taken during the first 24 hours, and 2 hourly temperatures during the next 24 hours. The pathogenesis of this early high fever is not known. It does not appear to be due to infection since in most instances there are no signs of spreading infection, either at the time of the fever or later. Pyrogens in intravenous fluids are responsible only occasionally. Shock and dehydration may play a role, but in many cases high fever is seen in the absence of these factors. Increased heat production due to the increase in metabolism as a result of extensive burns together with, and more important, the decreased ability of the patient to lose heat because of the greatly restricted area of exposed normal skin may be important. Walker and Shenken believe that in many cases the fever is cerebral in origin.

The burn patient cannot tolerate a high fever so that if the rectal temperature remains above 41 degrees C for more than a very few hours death is almost certain. Prompt and energetic treatment directed toward cooling the patient is effective in many instances and this treatment should be started whenever the rectal temperature is above 40 degrees C. If the fluids given have

been inadequate, more fluid will help but the main attention should be directed to ice water sponge baths to all exposed skin. If less than 50 per cent of the skin is exposed it may be necessary to remove some of the dressings. Windows should be opened, drafts created, bed clothes removed, and an ice water bath made in the patient's bed. He should be sponged for $\frac{1}{2}$ hour or more until the rectal temperature is brought to 39 degrees C but not below this.

PRIMARY LOCAL TREATMENT

A Introduction.

During the decade from 1930 to 1939, tannic acid, tannic acid and silver nitrate, gentian violet, and triple dye¹ displaced to a large extent all former methods of primary surface treatment of burns in the United States and Great Britain and its Dominions. From 1937 to date other forms of treatment have been advocated strongly and have now replaced the tanning methods as completely as the tanning methods replaced the older methods a few years earlier.

All methods of treatment of burns have always been based on an attempt to correct some one or more deleterious effects of the burn. Tannic acid was introduced to reduce the external fluid loss and to fix postulated toxins in the skin. The dyes were introduced to accomplish the same results and to furnish also an antiseptic action. In 1937 Allen and Koch introduced the now well known pressure dressing. They claimed that the pressure reduced both internal and external fluid loss and that infection was reduced by careful initial cleaning and by the rest and protection furnished by the bulky dressing. Originally no antiseptic except boric acid ointment was used.

With the introduction of the sulfonamides into medicine, they were immediately introduced into the treatment of burns. Pickrell used a solution containing sulfanilamide that was sprayed on to form a transparent eschar. Others used various sulfonamide ointments, or merely dusted on the drug and covered it with petrolatum or a bland ointment. Gurd combined the cleaning and pressure method of Allen and Koch with a sulfathiazole "cream." Others used preformed films containing sulfonamides (6). Whether or not sulfonamides were used on the surface they were also given by mouth or parenterally. New anti-bacterial agents, such as propamide, were discovered and used. Finally with the discovery

and production of penicillin, it was used locally and parenterally. In order to secure more complete rest and more even pressure, plaster casts were introduced to replace pressure dressings in some cases. Recently the washing of burns was given up by Cope (43) and washing, ointments of all kinds, and routine chemotherapy were given up by Levenson and Lund (117). Complete excision of small area burns on entry with immediate skin grafting has been carried out successfully. Delayed excision and skin grafting of more extensive burns have been used by Cope and Moore (46). Chemical excision of the burn with early skin graft was successful in serious cases (39).

There is still no general agreement as to primary local treatment. Recently however certain fundamental conceptions have been widely accepted and have led to a more nearly unified view of treatment. The first of these is that the cure of local areas in a patient with burns of any important size is but part of the total treatment of the patient. The second is that the treatment of the patient should be based on methods to correct as far as possible the many physiological and pathological changes brought about by the burn. Local plasma loss should be limited, further contamination prevented, and infection controlled. Any surface application should cause no local or general toxic effects. Application of the treatment should be rapid and relatively easy and the least possible attention should be required thereafter. It should be stressed, however, that no fixed routine can be established for all cases. An understanding of the underlying principles will make it clear when variation in methods should occur.

B Fluid loss

In addition to the harm done by the loss of fluid from the circulation by causing shock, the fluid is harmful to the subcutaneous tissues because it clots there and increases the extracellular pressure with resulting increased fibrous tissue (75). This results in subsequent impairment of function. This is evident particularly in burns of the hands in which it is often seen that following some dermal or deep dermal burns there is marked limitation of motion of the fingers. On review of these cases it is found that swelling occurs early and persists for some time. In contrast, it is found that in cases of similar severity in which minimal swelling has been prevented, function is unimpaired (74, 118). It is apparent, therefore, that from the point of view of both local and systemic reactions, one of the features to be desired of any local treatment is that it limit the amount of internal and external fluid loss.

¹The formula used under this name vary. One is:
Gentian violet
Resorcinol green
Acetic acid
Disinfectant water ad

1 Washing of burns. Washing of the burned area opens up previously closed tissue spaces and leads to a considerable increase in fluid loss, as was pointed out in the discussion of Chart 3. The relation of washing to infection will be discussed later.

2 Escharotics and pressure dressings and casts. Tannic acid and other escharotics until recently have been widely employed for primary treatment, in part because of their ability to prevent external exudation of fluid from the burned area. There is no doubt so far as the tannic acid and silver nitrate combination with its rapidly forming eschar is concerned that this end is accomplished. While the use of tannic acid is not desirable because of its toxic action on the liver nevertheless the necessity of prevention of external losses of fluid in occasional dermal burns may be judged from the following experience.

The patient was a 22 month old child weighing approximately 15 kilograms who was admitted to the hospital with hot water scalds involving 25 per cent of his body surface. The burned areas were oozing plasma at a rapid rate. There was very little subcutaneous edema. The surface was treated by the application of petrolatum and pressure bandages. The external loss of plasma was not arrested and the bandages continued to be soaked with fluid for at least 36 hours. During this time 8 units (2,000 c.c.) of plasma were administered with no hemodilution. This amount of plasma represented approximately three times the plasma volume of the child. In spite of this, shock occurred three times in the first day. Had it been possible to prevent the enormous surface loss this very large amount of plasma would not have been required.

It has been our experience that pressure dressings, or casts, applied over ointment, have very little effect on the amount of fluid lost externally while the agents which rapidly form eschars do stop surface leakage. However treatments aimed at sealing off the burned surface do not and cannot prevent the loss into the subcutaneous tissues. As pointed out by Underhill Harkins (87) and more recently by Glenn and his colleagues (75) this subcutaneous loss in deep dermal and deep burns is considerable and may surpass the external loss. The latter state that in one of their dogs with burns of the two front feet plasma equivalent to more than one-third of the animal's blood volume passed into the area from the tibiae to the humeroradioulnar joints.

An example of the failure of tannic acid to prevent internal fluid loss may be derived from a re-examination of Chart 2. Shortly after admis-

sion the patient was treated with tannic acid and silver nitrate solutions. Fifteen minutes after such treatment the external extravasation of fluid from the burned areas ceased completely and yet the rising hematocrit and hemoglobin showed that fluid loss continued for many hours. As a matter of fact the presence of increasing subcutaneous edema was easily discernible on physical examination. This subcutaneous loss of fluid has been minimized experimentally in dogs (74) and clinically in human beings, by the use of close fitting plaster casts (12, 116) and elastic pressure dressings (5).

C Local tissue injury caused by surface treatment

It is desirable that no further injury be imposed on the burned area by the agent used in the local treatment. It has been shown that the escharotics, as opposed to bland ointments injure viable epithelium. Partial thickness donor sites heal significantly faster under a firm ointment dressing than under tannic acid and silver nitrate or triple dye (29, 97). Healing of dermal burns of the back takes place a few days earlier if ointment is used rather than either tannic acid and silver nitrate or triple dye (36). Epithelialization under a dry gauze pressure (113) or saline pressure (143) dressing proceeds at the same rate as under a petrolatum dressing.

D Systemic effects of substances applied locally to the burned area

Absorption of certain types of substances from the surface of both second and third degree burns has been demonstrated (132). Therefore, it is important that any agent used in the treatment of the burned area either be not absorbed, or if absorbed, be relatively nontoxic. This is especially important when burns of a large area are being treated. Jaundice and other evidences of liver damage are seen more frequently in patients treated with tannic acid than in those treated with bland ointments (93).

Boric acid ointment has been used often in the local treatment of burns. Boric acid has no particular virtues and since it may be absorbed in toxic amounts if applied over a large area of injured skin (150) it had best be avoided and simple petrolatum used.

Sulfonamides in soluble form, if used locally may be absorbed in toxic amounts (120). Therefore if used the preparation should remain in effective concentration locally and yet not be absorbed rapidly enough to cause general systemic reactions. Since there is often early oliguria in severely burned individuals, the possibility of

kidney damage secondary to the sulfonamides is increased. A 5 per cent sulfathiazole emulsion from which the absorption is relatively slow has been used with good results (80)

E. Prevention of infection

Strict aseptic technique in the handling of burned patients is necessary to prevent additional contamination of the wound.

1. Washing and débridement of burns. Until recently the custom of washing and débriding burns had not been challenged. The characteristic view was that expressed in the following quotation "To cover a burned area with chemical or coagulating solutions without first using every effort to transform it into a clean wound seems to us inexcusable disregard of fundamental surgical principles (5). However it should be borne in mind that a burn is different from the ordinary soft tissue wound. Initial contamination is slight and it is rare that subcutaneous tissue and muscle are exposed. The type of débridement practiced in the primary care of soft tissue wounds cannot be carried out in any except very small burns. Even simple washing of a burn has certain disadvantages—the increase in time, fluid loss, handling, and pain—which make it preferable to omit washing if possible. Routine washing of burns has recently been shown not to be necessary if pressure dressings or casts are used (43, 116). However it is generally agreed by those who do wash burns that it should be done gently and quickly. White soap has been most commonly used rather than tincture of green soap.

2. Prevention of further contamination. It is essential that the area be protected from further contamination. When escharotics are applied, the eschar which is at first intact, soon cracks and further contamination is thereby possible. Pressure dressings or casts which remain dry on the outside prevent the entrance of additional organisms. If however the dressing becomes saturated with exudate contamination is possible. This has been minimized by the incorporation of a cellophane membrane in the dressing (143).

At each dressing change there is the possibility of further contamination. Consequently dressings should be done at infrequent intervals. The first dressing should remain in place for about 2 weeks. At the end of this time most dermal burns are healed and require no further dressing but deep dermal, mixed and deep burns are just beginning to slough so that additional dressings are required.

3. Immobilization. The importance of immobilization in the control of infection has been amply

demonstrated. The absorption of toxic products, metabolic or bacterial, depends to a large extent on the lymphatic flow which is reduced considerably by rest of the injured part (12). In contrast to surface eschara, pressure dressings with splints or close fitting casts provide for immobilization of the burned area.

4. Chemotherapeutic agents. These agents have been widely used for the control of infection of burns. The sulfonamides have been used both locally and systemically but their efficacy in controlling the local infection of the burn has not been clearly demonstrated. When one considers that there is usually a mixture of gram positive and gram negative organisms in the burned area, and, in addition, there is present considerable necrotic tissue and exudate it is not surprising that there is no striking control by the sulfonamides. In some instances it has been claimed that while the local infection is not controlled, spreading infection and blood stream invasion are prevented (135).

It must also be remembered that all deep burns will have an open wound harboring organisms until the last grafts have successfully healed and that this may take several months. As it is unlikely that any patient can tolerate effective doses of any sulfonamide for this length of time, it is recommended that no general sulfonamide treatment be given as a prophylactic measure or for any other purpose except for some complication such as pneumonia.

Penicillin has been used locally and systemically in many cases of serious burns (117, 96, 191, 22). When used locally it has the great defect of rapid absorption from the wound. To overcome this objection experiments are being made with special ointment bases such as carbowax¹ (136). With such a base some penicillin activity may be maintained for as long as 24 hours. A more serious defect is the rapid destruction of penicillin by the action of penicillinases released by bacteria, such as the colon bacillus, that are present in the wound and which are not sensitive to its action. When given intramuscularly penicillin has not been shown to reduce in any way the hemolytic staphylococcus infection of a burn. Possibly if such an infection were found in pure culture on a burn it might be effective for this purpose, but such pure cultures are seldom seen. Hirschfeld (96) stated that when penicillin was used before and after skin grafting better results were obtained. Levenson and Lord (117) found that it was possible that the change of

¹Carbowax is the name of a series of polyethylene glycols. They are water soluble but have the consistency of grease.

technique of dressing in the preparation for grafting associated with the use of penicillin was more important than the drug. On the other hand, in the few cases in which the cultures from a granulating wound that is ready for grafting in every other way show repeatedly that the hemolytic streptococcus is the only or predominant organism, general penicillin should be used in the dose of 25,000 units every 2 hours for 48 hours before and after the graft. Under this special condition it has been shown to be very useful.

F Technique of application of a pressure dressing

Under operating room conditions fine meshed gauze, dry or impregnated with petrolatum should be applied directly to the wound. Over this, sufficient sterile gauze, absorbent cotton, cellucotton, or mechanics waste should be placed so that even compression can be secured by means of a firm, wide bandage. If the padding is furnished in large rolls of material from 1 to 2 centimeters thick, 20 centimeters wide, and 4 meters long it facilitates the application. It should be emphasized that to be maximally effective the dressing should be applied as soon as permitted by the general condition of the patient, since the greatest amount of swelling occurs in the first few hours following injury. Also since the swelling is not limited to the burned areas, but occurs also in the immediately adjacent areas, these areas must be incorporated in the dressing. In burns of the extremities the dressing must extend distally to cover completely the hand and foot, even if these areas are not burned, otherwise the venous return will be obstructed, and as the back pressure builds up the arterial blood supply will be impaired. Elevation of the extremity may help to prevent stasis and discomfort. In applying a pressure dressing the tension must be uniform and care must be taken that no more pressure is used than is required. In burns of the chest and abdomen a pressure dressing as such cannot be applied without interfering with the patient's respiration. Therefore, in this location a firm bulky dressing without pressure is used.

G Technique of application of close fitting casts

The application of close fitting plaster-of Paris casts is recommended for burns of the extremities particularly for burns of the hands, but it is not recommended for burns of the trunk, buttocks or head. Under operating room conditions, one layer of sterile fine meshed gauze, dry is applied to the entire area to be covered by plaster. This is covered with four layers of sterile open mesh gauze, fitted carefully without overlapping.

Plaster slabs are then molded over the extremity front and back. A thin layer of rolled plaster completes a nearly skintight, light, well fitting plaster cast. The cast must be close fitting but must be applied without compression at any point. As in the case of a pressure dressing it should extend proximally from 7 to 16 centimeters beyond the limit of the burn. In burns of the extremities it must extend distally to cover completely the hand and foot (including the tips of the fingers and toes) even if these areas are not burned otherwise the circulation will be seriously impaired. Hands should be put up in the position of function with a slight cock up at the wrist and fingers in neutral position. It is all important that directions be followed exactly (12, 116). Levenson and Lund have seen instances in which improperly made casts had to be removed to prevent gangrene.

H The use and technique of petrolatum gauze dressings

Allen and Koch Cope (42) and others advise pressure dressings for burns of the face, head, and neck, as well as for those of the trunk and extremities. After using them on a number of patients Levenson and associates (113) have given them up in treating these particular burns. Two reasons led to this decision. First, such dressings were always uncomfortable when used for serious burns. Second, sufficient pressure could not be used to control the edema of the face or neck. They now use sterile petrolatum gauze strips applied without pressure and without bandage. These strips rub off from time to time and new ones are put on by a nurse. They are rectangular and approximately 8 by 16 centimeters. They are made of fine mesh cotton bandage material impregnated with petrolatum and sterilized. Other areas where pressure dressings are impractical are the genitalia and the anus. Petrolatum strips are also used there.

When this treatment is used, the hazard of contamination is increased. However this has and is great in burns of these areas with any known treatment. It may be reduced by isolating the patient, by using sterile bed clothes, and by careful aseptic nursing procedures.

SECONDARY SURFACE TREATMENTS

The first pressure dressing or cast should be left in place for 2 or 3 weeks except in the few very superficial dermal burns that have probably healed prior to this time. A foul odor contamination of the dressing by urine or feces, and evidence of infection under the dressing should rarely be

considered indications for a change at any earlier time. If the dressing becomes loose or slips it should be repaired by adding more sterile material, new outside bandages, and new adhesive.

Changes of dressing should be made under aseptic conditions in an operating room. The patient should usually be prepared by a mild sedative. Anesthesia may be needed in rare severe chronic cases at many late dressings. Cyclopropane is the anesthetic agent of choice. On removal of the dressing the status of the wound is appraised and the further needs of the patient are estimated. Dermal burns will usually be healed in 2 weeks but deep dermal, mixed, and deep burns will be covered with soft foul slough. Purulent material and loose slough may be wiped off gently but no antiseptic solution should be used. In these cases some remaining slough will be present from 20 to 40 days. The second and all subsequent dressings should also be pressure dressings applied with the same technique described. As soon as large areas have become free of slough and if the granulations and the patient are both in good condition grafts should be applied without waiting for the adjacent slough to separate. In addition to the "chemical débridement" which will be described, many varieties of dressings have been suggested to speed the separation of the slough as well as to control infection. In general, every method, and this includes the one recommended here, has disadvantages as well as advantages. Frequent changes of dressings, wet, dry or with ointments, traumatize the wound and increase the danger of bacterial contamination, and the process of changing them is wearing to the patient. Antiseptic solutions or ointments may injure the granulations, the patient, or both and never eradicate infection. Pressure dressings applied to several extremities produce such immobility of the patient that he loses strength rapidly. On the other hand less confining dressings fail to control the pain from friction and allow more contamination. Both are weakening.

Tub baths and shower baths have been recommended (137). In general these are difficult to arrange and are infrequently used at present in the United States. A good method of providing continuous or intermittent irrigation with saline or Dakin's solution of the extremities has been devised by Bunyan. He uses a transparent plastic envelope that has two rubber tubes sealed into its sides. It is troublesome to use.

During the last years Levenson and associates (113) have abandoned all previous forms of secondary treatment and apply infrequently changed

dry pressure dressings or casts to the extremities and similar nonpressure dressings to the trunk. Even the use of frequently changed wet dressings just prior to grafting has been discarded (117). The only exception to this treatment of these areas is when very small scattered areas of granulation are left at the edges of the grafts. Under these conditions nonpressure frequently changed petrolatum dressings are used.

SKIN GRAFTING

Until the advent of the Padgett dermatome the technique of skin grafting burns of large area was difficult and was mastered by few surgeons. The simplest technique, but least satisfactory is that of Reverdin. Somewhat more difficult, but more satisfactory is that of Thiersch and much more difficult, but most satisfactory if successful, are the whole thickness graft and the pedicle graft. There is a great tendency particularly among surgeons who treat burns only occasionally to wait many months before doing any graft to allow nature to make its maximum efforts at healing. With such a *laissez-faire* policy burns adjacent to the joints lead to crippling contractures and deformities.

If Reverdin grafts are used early placed closely and tacked, they will grow out, cover large areas and at least in part, avoid contractures. However the skin surfaces (both recipient and donor) are always 'spotty' and seldom satisfactory. Expertly cut Thiersch grafts stretched to normal tension and completely covering a noncontracted granulating surface are much more satisfactory. In fact, the grafted skin approaches normal skin in appearance and function, and the donor site often becomes invisible.

Whole thickness grafts are of very little importance in the treatment of large burned areas. For small specialized areas, such as the eyelids, face and neck, they are essential, but the care of such defects is in the field of much more specialized plastic surgery than is within the scope of this review. The same is true of pedicled grafts.

1. Immediate excision and skin grafting

Immediate excision and skin grafting has been carried out by several authors (197). It is theoretically sound because after a deep burn is excised and the wound grafted, the area is healed in a week or 10 days. However it has a very limited applicability and is indicated only in obviously deep burns of very small area in which there is little likelihood of shock. Relatively few deep burns come in this category. Even with a small burned area the operation is a long one be-

cause of the difficulty of securing complete hemostasis.

B Delayed excision and skin grafting

Delayed excision and skin grafting has been carried out recently in a number of cases by Cope and Moore (46). It is their practice to give large amounts of penicillin intramuscularly and locally through Dakin's tubes incorporated into a pressure dressing at the time of burn. From 3 to 7 days later when the shock has been satisfactorily treated and the general condition of the patient is good the burned area is excised and grafted at one operation or grafted later within a few days. If the area is very extensive, the procedure must be done in stages. The same procedure, begun at a later date, between the tenth and fourteenth days, has been followed by Ackman and his associates (3). In their technique no parenteral chemotherapy is given but a sulfathiazole emulsion is used locally. The results of these procedures have been excellent, and the method has great promise in the hands of surgical teams experienced in dermatome grafting operations and in the care of surgical shock. Blood transfusions to the amount of several liters may be needed at the time of and immediately after these operations.

C Skin grafting after sloughing

Burns are grafted in most clinics in the granulating stage. The time when the slough is completely separated is usually between the third and sixth weeks. Sloughs on small and more vascular areas, such as the face, separate more quickly than those on larger and less vascular areas. Recently attempts have been made to speed up the time of separation of the slough by the application of various solutions such as the proteolytic enzymes, papain (41) or pepsin (100), or by the application of pyruvic acid in a starch paste (39) (chemical debridement). With the latter method the sloughs of deep dermal and deep burns may be removed in from 6 to 10 days without injury to any epithelium that may be present in the more superficial areas, or to the granulation tissue. Some very impressive results of its use in severe burns have been reported.

When the condition of the patient is satisfactory the granulations are firm and pink, and the chances of successful skin grafting are good. When unsatisfactory the granulations are edematous and friable, and the chances of successful skin grafting are poor. In most cases granulation tissue is not removed. However exuberant but firm granulations, if removed down to a firm yellow

low base, are no contraindication to grafting. Bleeding is controlled by warm saline packs or the application of thrombin (51).

D Technique of dermatome skin grafting

The Padgett dermatome (145) has many advantages over the knife or razor for cutting Thiersch grafts. Sheets of even thickness may be cut from parts of the body that could not otherwise be used as donor sites. Any thickness of skin, from 0.15 mm. to full thickness of the skin, may be taken. Grafts should be between 0.15 and 0.30 mm. thick. The amount of skin transferable at one operation is limited by the patient's general condition. Patients should seldom have more than four drums of skin grafted at one operation. Very sick patients can tolerate only two drums.

1. *Anesthesia.* Although it is possible to cut grafts after infiltration of the skin and subcutaneous tissue with procaine it is much more time consuming and difficult than to cut them under general or spinal anesthesia. Patients with extensive wounds do not tolerate either nitrous oxide and oxygen spinal or pentothal anesthetics well. Cyclopropane is much safer and is very satisfactory. Levenson and his associates (113) have used it in several hundred operations without any complication.

2. *Choice of donor sites.* Any part of the trunk, the whole circumference of the thigh or arm, and the posterior surface of the calf may be used as donor sites. Smooth areas on the thighs, chest, abdomen and back that are not too hollow or too sharply rounded are the areas most easily used. If the patient cannot easily remain prone for a few days, use of the back will cause post-operative discomfort.

3. *The operation.* Before the patient is anesthetized the dermatome knife should be inserted in its slot with the bevel away from the drum and its edge adjusted to cut the desired thickness of skin. This is done by setting the flange plate at zero and bringing the blade flush with the drum by turning the two adjusting screws at the sides. Then, turning the flange plate the required number of graduations will set the blade at the correct distance from the drum. The flange plate is graduated so that one division equals 0.025 millimeter. While the patient is being anesthetized the donor site is prepared with any standard method of skin preparation. If the wound dressing is removed at this time care must be taken not to contaminate the donor site, the instruments, or the team that will take the graft. After sterilization the donor site must be washed care-

fully with ether to make the skin absolutely dry. Then the drum is coated with an even thin layer of the special rubber cement that is furnished with the dermatome. Another layer of cement is then put on the dry skin. This is allowed to dry for from 2 to 3 minutes until it has lost its shiny moist appearance. The dermatome is then grasped in the surgeon's left hand with the back of the blade resting on his wrist. The distal edge of the drum is placed on the distal edge of the donor site and pressed down firmly for 1 minute. The edge is then raised about $1\frac{1}{2}$ centimeters by rolling the drum. The blade is then brought into contact with the skin by the right hand. Cutting is accomplished by short quick strokes of the blade while the left hand rolls the drum slowly toward the proximal edge of the donor site. The skin in contact with the knife should be under slight tension by being lifted by the adherent cement, while the skin about 3 centimeters proximal should be compressed by the drum. After from 1 to 2 centimeters have been cut an assistant should inspect the graft to determine its depth. If it is not correct the cut may be made thicker or thinner by moving the flange. This is done without removing either the drum or the blade from their positions. At times it may be necessary for the assistant to press down on the skin just lateral to the drum to keep this skin from interfering with the stroke of the knife or from being cut irregularly. When the proximal edge of the drum is reached the graft should be cut free with a separate scalpel. It is then picked up with small hemostats, peeled off the drum and laid on a sponge moistened with saline solution. Powdering the upper surface which is sticky from the rubber cement with sulfanilamide will make it much easier to handle. Other grafts are then cut if necessary. After all the grafts to be used are cut, the donor sites are covered with one thickness of fine mesh nylon or rayon and a few layers of gauze and towels to protect them from contamination during the remainder of the operation.

The area to be grafted is then uncovered, the skin around it sterilized and draped, and the wound surface is cleansed by applying moist sponges which are then removed without rubbing. The grafts are then laid on the wound in the largest possible pieces that fit. When the areas to be grafted are small or irregular in shape the grafts should be cut into pieces that fit. When ever possible, the grafts should come at least to the edges of the wound, and preferably they should overlap the edges slightly. Unless the method of using a "backed" graft, which will be described, is used, the graft should be stretched

to normal skin tension by sutures from 5 to 6 millimeters apart around its edges. A pressure dressing over the graft, which is strapped and bandaged into place so that it cannot possibly slip is essential. If the graft is on an extremity a plaster cast fixing the joints above and below the area grafted is also important.

The donor sites are now bandaged over the temporary dressing. If the donor site is on the anterior surface of the body arms, or legs, the whole dressing should be removed down to the single layer of nylon or rayon as soon as the patient is in bed. This should be exposed to the air to allow a dry scab to form which will protect the wound. This should be left in place until it falls off spontaneously after healing has taken place in 3 or 3 weeks.

4. Backing for dermatome grafts (78) The technique just described gives very satisfactory results but is time consuming because in order to stretch the grafts properly it is necessary to use a great many sutures. Usually the suturing is the longest part of the operation. When the grafts must be subdivided it is especially difficult to handle the pieces. Webster has recently shown that 'pilo film' may be used as a backing for grafts, and Evans (64) has suggested cellophane for the same purpose.

Before a graft with a backing is cut the drum is coated with dermatome cement and the backing film cemented to the drum as smoothly as possible. New coats of cement are then applied to the film and to the donor site and the graft is cut as described. The graft with its backing is removed from the drum and is placed on the recipient site. The backing prevents the normal contraction of the skin that results from its elasticity and gives it added strength. The handling of the cut skin is consequently much easier and any cutting of pieces to fit small or irregular areas is more easily performed. More important, however is the fact that no sutures are needed to maintain the graft at its original size and tension. The graft is maintained in place by even elastic pressure provided by a suitable pressure dressing. The backing is easily peeled off after the graft has healed.

Experience with cellophane as a backing material has shown that it is difficult to apply this substance to the dermatome without its wrinkling. Even very small wrinkles cause irregularity in the thickness of the graft. A more serious difficulty is due to the relative "stiffness" of the cellophane and the graft. When attempts are made to fit the cellophane backed graft to sur-

⁷⁸The film is the trade name of smooth plastic film that is relatively flexible.

faces that are convex, concave, or irregular wrinkling frequently results. This may lead to areas where serum or blood collects beneath the graft because of poor approximation to the granulations and over these areas the graft may be lost.

Fine gauge nylon¹ or similar rayon has proved to be more useful than cellophane. In the first place it never wrinkles on the dermatome drum. Secondly it sterilizes as easily as any textile and does not need special packing in the sterilizer to prevent adherence of its adjacent surfaces. It is unchanged physically after sterilization. In spite of its relative limpness before it is attached to the skin, it prevents contraction of the graft and sutures are unnecessary. Grafts backed with nylon conform better to irregular surfaces than do those backed with cellophane. In addition it has been found that it is possible to cut the skin from 0.15 to 0.20 millimeters thick. Such grafts are slightly thinner than those which can be successfully cut and handled without backing. The donor sites from which such thin grafts have been taken heal very rapidly and can be used again in a relatively short time. On all areas where split thickness grafts are satisfactory grafts of this thickness have given as satisfactory end results as slightly thicker ones.

E. Homografts

Homografting or the use of skin from some one other than the burned individual is in the nature of a temporary dressing since such grafts disappear in from 3 to 6 weeks. The only permanent homografts have been transplanted from one identical twin to another (23). The blood group as such appears not to have any important bearing on the success or duration of this type of graft. Homografting has a limited but definite application in the care of patients, particularly children with extensive burns. With the granulating areas covered, though only temporarily the general condition of the individual improves so that by the time the grafts dissolve autografts may be made. Ackman (2) has had a large series of cases in which these grafts were used successfully.

NUTRITION

As noted in the earlier section on nitrogen metabolism there are great early losses of nitrogen in the urine and losses from the surface of the burn until epithelialization is complete. The fact that low plasma protein levels and hypoproteinemie edema occurred late after burns was noted by

several investigators between 1930 and 1940. A fine report on this subject was that of Clavelin and Hugonot. There was very little of practical value that could be done at that time to improve the nutrition of their patient and an amputation had to be performed. When human plasma and serum became available they were used to combat this nutritional edema and following the attack on Pearl Harbor they had their first large scale clinical trial for this purpose. The results of plasma treatment of patients with edema were in no way as striking as the results of treatment of shock in burns. Plasma is inadequate as a means of combating the edema, which is a nutritional edema, because of the small amount of protein furnished by large amounts of plasma when compared to the needs of the organism. One liter of therapeutic plasma contains only about 50 grams of protein which as will be indicated is only a small part of the nutritional need of the patient with edema.

The estimation of the status of a burn patient with regard to the presence or degree of protein deficiency is not simple. The factors necessary for a critical evaluation are (1) optimum weight of the patient, (2) observed weight of the patient, (3) plasma protein level, (4) plasma albumin level, (5) plasma volume, (6) nitrogen intake and (7) nitrogen output. Actually, main reliance in clinical work has to be placed on a nutritional history on the patient's weight, and on serum protein determinations done most simply by some densitometer method.

Elman (60) was the first to stress the patient's weight in evaluating protein depletion. It is practical to weigh bedridden burn patients by weighing them on a stretcher at the time of dressing changes just before the dressing is removed and then weighing the removed dressing and the stretcher. As soon as a surgeon commences to weigh his patients with burns he will be amazed at some of the losses encountered in patients that do not have very severe burns. Losses of more than 25 kilograms have been reported as occurring in a few weeks after a severe burn in spite of efforts to maintain nutrition (178).

Failure to meet the increased nutritional demands of the severely burned patient results in progressive loss of weight and strength, edema, friable granulations, increased local infection and, finally, death from malnutrition. It is preferable to anticipate the requirements of the patient and to meet them before severe malnutrition occurs. In the very severely burned patient this may require as much as five or more times the normal intake of nitrogen. It has been indicated that the principal

¹This is the 55 gauge nylon cloth used for parachutes. It is not more than 1 millimeter thick and has a strength of 50 pounds per square inch in each direction. The warp is made of 40 Denier threads, 7 threads to the inch, and the weft of 40 Denier threads, 16 to the inch.

foodstuff required is protein. However, the food provided must be an adequate metabolic mixture containing in addition to adequate amounts of protein sufficient calories, carbohydrates, minerals, water and accessory food substances. Whenever possible, protein losses or deficiencies should be corrected by oral feeding. It is not enough for the surgeon to order a "high protein, high caloric, high vitamin diet." If such a diet is ordered the patient may fail to benefit from the order for any one of the following reasons: (1) the diet presented to the patient is not as specified; (2) the diet presented is not eaten in whole or in part because it lacks palatability; there is lack of appetite, and there is a lack of nurses to encourage eating; and (3) food eaten may be partly or wholly lost because of diarrhea or vomiting.

The three items listed under No. 3 are interrelated. It is common experience to find that a sick patient has no appetite. However, if special attention is paid to the likes and dislikes of the patient and special or other nurses are available to encourage eating and to offer meals when the patient desires them instead of only at stated routine periods, many such patients will eat a surprisingly large amount of food.

The two items under No. 3 are also related to each other. Forcing the diet in a sick patient does not always result in a net gain. Nausea, vomiting, distention, and diarrhea singly or together are limiting factors. In general the sicker the patient the less fat is tolerated, and the larger the proportion of protein that is required. It has been found that at least 25 per cent of the calories in the diet should come from protein and not over 15 per cent from fat if any of these intestinal symptoms have occurred recently. Some patients will need 50% of their calories in the form of protein. It is well to take a number of days to increase the food intake, as sudden increases are more likely to be followed by gastrointestinal symptoms. More cautious increases will prevent such symptoms. If the diet is not tolerated, protein in the form of a digest should be tried and frequently will be well tolerated. The available digests are not particularly palatable and should be given by intubation if refused by the patient.

Intubation feeding is important and may be used to increase the intake of food greatly. Medium caliber nasal stomach tubes are used and left in all the time or for many hours a day. If left in continuously the tube should be removed every third or fourth day for cleansing. About 500 cubic centimeters may be given at a time, spaced between meals and at night but there is a

wide variation in the amount and frequency of supplementary tube feedings that different patients will take. It is well to start with half skimmed milk and half water or with a mixture of protein hydrolyzate and carbohydrates and increase the strength and quantity of the mixture over a period of days. Instead of supplying the mixture in intermittent doses, a drip apparatus may be used which can, after a short period of training, be regulated by some of the patients themselves. If from 125 to 150 grams of protein and from 2,000 to 3,500 calories are given by intubation in addition to an average house diet, the patient should receive a total of about 200 grams of protein with over 4,000 calories.

Some of these patients will require protein and carbohydrate supplements given intravenously as well as by intubation. This has already been discussed by Tagnon and associates (173) and by Lund and Levenson (125) and by Elman (59).

CHRONIC ANEMIA

As noted in an earlier section there is an acute hemolytic process starting immediately after an extensive deep burn and continuing for about 72 hours. The actual number of red blood cells hemolyzed during this period is usually relatively small. However following this there is a chronic anemia which continues until healing is complete.

This anemia is progressive and its chronicity and severity are roughly proportional to the extent of unhealed deep burn. It does not respond to large intakes of iron, liver extract, protein, calories, and vitamins, although these must be given for nutritional purposes. Blood transfusions are necessary at frequent intervals and in large amounts to maintain the hemoglobin at a satisfactory level. In the past it has usually been recommended that the burn patient should be transfused with type specific blood when the hemoglobin falls below 75 per cent, but it has been learned that he does better when his hemoglobin is kept above 85 per cent. To accomplish this may require as much as 1 liter or more of blood every week during the patient's entire course of illness. If available, red blood cells suspended in saline solution are as satisfactory as whole blood (172).

The cause or causes of this chronic anemia are poorly understood. One factor may be chronic hemolysis. In support of this concept Moore and Cope (46) have found an increased excretion of red cell breakdown products. Emerson and Ebert recently demonstrated that pooled plasma and type O whole blood given to patients with types A, B or AB blood induces a persistent and severe

hemolytic process. This is detected by finding an increase in bilirubin in the plasma. Hemoglobinemia and hemoglobinuria are not found. Another factor in some cases is loss of blood into the dressings. This is particularly marked when the granulations are 'poor' and edematous in patients that are not in nutritional balance. The bone marrow is not markedly depressed as the reticulocyte count frequently reaches 5 per cent.

SEX HORMONES

In severe burns in young women menses cease and do not commence again until healing is nearly complete. At the same time these patients develop an abnormal growth of hair especially on their arms and legs. This hair disappears about the same time menses recommence (115-47). No similar change is noted in men. Attempts to treat the metabolic effects of burns with a growth promoting sex hormone (testosterone) in the early stages have not met with success (24-95). Recently following a suggestion made by Browne (24) testosterone propionate has been used with considerable clinical success in the late stages of burns at the Boston City Hospital. It was not possible to study the nitrogen excretion in these cases, but clinically they responded in a manner that indicated an increased positive nitrogen balance. The pain decreased, the granulations improved, the appetites increased, and weight was gained very rapidly. The dose used was 10 milligrams per day given intramuscularly. This hormone has given this good effect to patients of both sexes.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Donegan, E. A.: Ocular Findings in Tropical Typhus (Tautauganuah or Japanese River Fever) *Br J Ophth* 1946 30 11

Donegan reports the ocular findings in a series of 101 cases of tropical typhus or Japanese fever at the India Burma border. The disease is closely related to the louse-borne typhus which occurred during World War I (1914-18) in the Balkans and in Russia, and during World War II in Italy as well as the tick-borne typhus throughout the world. Rickettsia orientalis is the causative organism and its insect vector is a mite that is usually found where there is dead wood low scrub and rotting vegetation. Tropical rats and birds are the reservoirs of the disease.

Ninety-six West Africans and 6 Europeans were affected. The patients usually presented headache, apathy, enlargement of the spleen and liver, pulmonary congestion, hyperemia of the conjunctiva, blurring of the margins of the optic disc, optic neuritis and hardness of the vitreous. Many cases showed evidence of the descending neuritis described by von Graefe which disappeared without residual damage to the optic nerve or retina.

There were only 2 cases of optic atrophy in the present series 1 of which was syphilitic. The mortal rate was 4 per cent. JOSEPH ZUCKERMAN M D

Paul M.: Cavernous Hemangioma of the Orbit Successfully Removed by Shingue's Operation *Br J Ophth* 1946 30 35

The author describes a cavernous hemangioma of the orbit which was successfully removed by Shingue's method of operation which involves an approach to the lateral wall of the orbit beneath the zygomatic bone removal of the lateral orbital wall and removal of the tumor. The major complication of this operation is the possibility of injury to the lateral rectus muscle. The advantage is in the adequate exposure of the tumor which does not interfere with the future function of the eye. In the author's case removal of the tumor gave a satisfactory result.

HOWARD H. ROBERTS, M D

Meenan, P N.: The Etiology of Trachoma in Ireland (Preliminary Communication) *Iris J Med Sc* 1945 839 370

The author discusses the etiology of trachoma in Ireland, where it has recently become prevalent. He points out that trachoma causes approximately 9 per cent of the cases of blindness in Ireland but only 0.81 per cent in Scotland.

At present, the causal agent of trachoma is considered to be either a rickettsia or a virus. There is some evidence in favor of the rickettsial theory. Typical rickettsias are not filtrable and they confer immunity.

There is also evidence in favor of the virus theory which was advanced in 1907. The infective agent is filtrable. The presence of inclusions composed of elementary bodies constitutes the earliest recognizable change in trachoma and is demonstrable in all cases at their onset.

Whether viral or rickettsial in origin these bodies are considered the causal agent of trachoma. They are morphologically indistinguishable from those of psittacosis inclusion conjunctivitis and lymphogranuloma venereum. The virus has never been grown in the laboratory. Infection with trachoma does not confer permanent immunity.

It seems that the Castaneda positive viruses are closely related. They may all have a common ancestry and the specific differences may have been acquired by prolonged residence in a particular animal species or tissue. JOSEPH ZUCKERMAN M D

Pereira R. F. and Tolosa, E. E.: Dacryocanalitis Simulating a Dacryocanalicularitis (Dacryoductitis simulando una dacriocanalicularitis) *Sem med. B Air* 1945 55 893

The author describes a rather remarkable case in which pus from the ethmoid cells was draining through a fistula from the involved sinuses and then through the superior lacrimal canal into the right eye.

Fluid instilled into the incised inferior lacrimal canal which contained a slight amount of pus passed readily into the nasal cavity apparently through the normal opening into the nose then the superior canal was incised but no pus could be expressed from the lacrimal sac. A probe was passed into the nasal cavity in the region of the ethmoid cells and its position verified with x rays.

The patient was now referred to the ear nose, and throat department, where the condition was diagnosed by direct examination as hypertrophy of the right superior turbinate due to edema of the meatus on the right side and by roentgenography because of the opacity of all the sinuses on the right side—especially the ethmoidal and maxillary—as a maxillo-ethmoidal sinusitis. An operation designated as that of Ermiro de Lima was performed. This operation permits supervision of the maxillary sinus and at the same time gives access to and permits evacuation of the entire ethmoid system. At this operation there was encountered intense hyperplasia of the

mucosa of the ethmoid cells. These cells were full of fetid pus and their intercellular walls were broken down.

In a few days the patient had healed normally with disappearance both of the secretion into the conjunctival sac, and of the fistulous opening into the nose. Re-examination a few months later disclosed complete absence of all signs of infection of the nose and eye. Fluids passed normally into the nose through both the superior and inferior lacrimal canals and the probe could no longer be passed through the fistulous opening into the ethmoid region of the nose.

JOHN W. BARNARD, M.D.

De Roethth A.: Hypofunction of the Lacrimal Gland and the Sjögren Syndrome. *J. Lencet* 1945, 68: 423.

The author states that diminished lacrimal secretion may be due to congenital absence surgical removal, or destruction (by radiation) of the lacrimal gland, the presence of toxins, and endocrine dysfunction.

The most marked form of hypofunction is known as filamentary keratitis. The condition is characterized by epithelial filaments which present knobs at their free ends. The less marked type is called keratoconjunctivitis sicca, which presents a stringy,ropy mucoid discharge, photophobia, burning, grittiness, round gray epithelial dots, and xerosthemia of the cornea. The Schirmer test shows only from 3 to 6 mm. of moistening in 5 minutes.

Another type of hypofunction occurs as part of the Sjögren syndrome in association with dryness of the mouth, nose, and larynx, due to decreased function of the salivary glands. About 50 per cent of patients with this type of hypofunction have chronic arthritis.

The mildest form of hypofunction is difficult to recognize. It is characterized by vague symptoms such as fatigue or heaviness of the eyes, dryness of the nose and mouth, and difficulty in reading especially by artificial light. However the Schirmer test is positive.

Therapy consists in occlusion of all the puncta, the instillation of tear substitutes such as sodium chloride, egg albumin, liquid petrolatum, fibrolysin or Gifford's solution, the administration of ovarian extract, and the removal of foci of infection.

JOSEPH ZUCKERMAN, M.D.

Hymes, C.: Scleral Flap Incision with Scleral Sutures for the Cataract Operation. *Arch. Ophth.*, Chic., 1945, 34: 374.

The author describes a method of cataract extraction in which a scleral flap incision is made and scleral sutures are used.

After retrobulbar injection anesthesia and akinesia of the orbicularis muscle, a superior rectus muscle suture is inserted for retraction of the eyeball. A conjunctival flap is dissected 3 mm. above the upper limbus, and a concentric wedge shaped scleral flap with its base at the limbus, is then made with the

use of a Lundgaard or Hymes concave knife. This is started at about 1 to 3 mm. above the upper limbus and the conjunctival flap is left attached to it. The corneal section is then made with a keratome and enlarged with scissors. Before extraction of the cataract, a single suture is inserted—first through the conjunctiva, then through the lower lip of the sclera, the upper lip of the sclera, and finally through the upper lip of the conjunctiva. The loop is laid aside. After the cataract has been extracted the suture is pulled taut, and tied.

The author is of the opinion that with this procedure, a firmer and more accurate closure of cataract wounds is obtained and the incidence of post-operative complications and of astigmatism is reduced.

JOSEPH ZUCKERMAN, M.D.

Chamlin, M.: The Effect of Talc in Ocular Surgery. *Arch. Ophth.*, Chic. 1945, 34: 369.

The author discusses the effect of talc (generally used on surgical gloves) on the ocular tissues.

In a series of experiments on the eyes of rabbits he simulated the accidental introduction of talc into the ocular tissues during surgical procedures. He found that talc produces foreign body granulomas in most eyes.

To avoid this undesirable possibility, he recommends directing a stream of saline solution from an irrigator at the surgeon's gloved hands before operation, instead of immersing them in saline or other solutions.

JOSEPH ZUCKERMAN, M.D.

RAR

Conley J. J.: The Treatment of Chronic Suppurative Otitis Media with Penicillin. *Arch. Otolaryng.* 1945, 4: 374.

Penicillin therapy is of little help in patients with chronic suppurative otitis media which has proved resistant to sulfonamide compounds. The response of chronic suppurative otitis media to systemic treatment with sulfadiazine followed by 1,000,000 units of penicillin is insignificant. The response of chronic suppurative otitis media to local penicillin therapy is good. 55 per cent of the cases treated were definitely improved. Granulation tissue and cholesteatomas are not affected by sulfadiazine or penicillin, whether administered generally or locally.

The best treatment for acute and chronic suppurative otitis media is to prevent their occurrence by the prophylactic use of one or both of the chemical and biological therapeutic agents.

NOAH D. FABRICANT, M.D.

Moreira, D.: Gradengio e Syndrome (Sindrome de Gradengio). *Fol. med. Rio.*, 1945, 56: 46.

The author reports on a patient with a syndrome consisting of acute otitis media, neuralgia of the trigeminal nerve, and paralysis of the sixth pair of cranial nerves, which was first described by Gradengio of the Royal Academy of Turin in 1904 and since then known under his name. This is the tenth case

SURGERY OF THE HEAD AND NECK

reported in the Brazilian literature and possibly the first from Brazil with contralateral paralysis.

The patient was a Brazilian mulatto 30 years of age who had atrophic rhinitis and upon admittance had been suffering with a suppurating left ear for about 20 days. After repeated myringotomy and intensive treatment with 4 and later 3 gm. per day of sulfanilamide the condition improved, but some-what over a month later intense temporal and retrobulbar headaches occurred and paralysis of the abducens nerve developed all on the right side. At no time did otoscopy or roentgenography show any evidence of changes in the right ear or other (mastoid or petrosal) regions. There was some doubt at this time of any changes in the mastoid cells of the left side and there was a slight mucoid discharge from the left ear but nothing suggested the sudden change in the patient's condition.

Treatment with sulfanilamide combined with antipyretic vaccine and vitamin B was instituted and 3 months later the patient was entirely well, and 5 months later the patient was entirely normal.

An interesting coincidence was the sudden occurrence of fever about 10 days before recovery with the discovery of plasmodium vivax in the blood. Altogether, the patient had undergone 8 myringotomies and received 15 ampoules of antipyretic vaccine 418 milligrams of vitamin B and 51.75 grams sulfanilamide.

NOSE AND SINUSES

Cenget, D. D., Poser, R. A., and Soet, A. Rhinosporidium Seebertii Granniloma. The First Case in Tucumán (Primer caso en Tucumán de granuloma por rhinosporidium Seebertii). *Arch. farm. biol. quim.*, Tucumán, 1945, 2: 19.

The authors report a new case of granuloma produced by the rhinosporidium Seebertii, the seventh case reported in Argentina, and the first found in Tucumán. It shows a geographic zone so far unknown with regard to this parasite.

This parasite is a fungus of the order of the chytridiales, belonging to the diploidiaceae family. The mechanism of human infection as well as that of infection of possible intermediary hosts is unknown. The fungus produces a chronic inflammatory hyper trophy which results in polyps of the nasal mucosa. Photographs of microscopic sections in the original article show all the developmental phases of the parasite.

HENRIQUE LANA, M.D.

Peor, L. A.: The Neglected Septal Cartilage Graft with Experimental Observations on the Growth of Human Cartilage Grafts. *Otolaryng.*, Chic., 1945, 41: 384.

The general belief that autogenous septal cartilage grafts do not survive after transplantation alar cartilage, lateral cartilage, and rib cartilage all survive after transplantation as living purposes. Autogenous sep-

tal cartilage is superior to alar and auricular cartilage only because of its greater bulk and firmer structure. It is superior to rib cartilage because it is more readily obtainable. Autogenous septal cartilage should be used whenever a nasal defect can be adequately supported by the patient's septal cartilage with the addition of septal bone when necessary.

When the nasal depression is sufficiently large to require rib cartilage, autogenous cartilage is the material of choice. Preserved cadaveric cartilage may be used in debilitated or elderly patients. Experimental observations indicated actual growth of young human annular and septal cartilage increased. The more bulky young rib cartilage grafts increased in some cases and in others showed no increase in size. Septal bone grafts without periosteum transplanted beneath the abdominal skin retained their normal bone structure for periods up to 4 years after transplantation. Rib and tibial bone, with and without periosteum transplanted beneath the abdominal skin completely disappeared 7 months after trans-plantation.

Berger, M. D.: Neoplasms of Both Maxillary Sinuses. *Arch. Otolaryng.*, Chic., 1945, 41: 397.

Because of the apparent rarity of cases in which both maxillary sinuses were invaded by neoplasms a careful scrutiny of the literature was undertaken in order to determine whether any such case had been previously reported. During the past 20 years there has been no report of a case of bilateral neoplastic involvement of the antrums. The author observed cancerous involvement of the two maxillary antrums in a patient 62 years of age. The neoplasms were separate and distinct entities. The second growth developed while the patient was under observation.

NECK

Leeson, M. F. and Gargill, B. L.: Thyrocarcinoma as a Cause of Neutropenia and Agranulocytosis. *N. Engl. J. Med.*, 1945, 233: 803.

The authors treated 62 patients with thyrocarcinoma. Of these, 61 had thyrotoxicosis and 1 had angina.

pectoris. Five patients developed neutropenia and granulopenia. Of these 1 (with thyrotoxicosis) died of agranulocytic angina; another of the 3 patients developed a sore throat but recovered; 1 patient, with granulopenia, recovered with continued administration of thiouracil.

Fifty-four cases reported in the literature, and 3 personal cases of neutropenia following the administration of thiouracil, are classified in 3 groups, as follows:

Group 1 includes 36 cases of asymptomatic neutropenia and granulopenia (often confused with the mild neutropenia and lymphocytosis of toxic goiter); group 2 includes 11 cases of significant neutropenia, frequently associated with symptoms, especially fever and pharyngitis, which readily subsided on discontinuance of the drug; the patients sometimes recovering with continuation of the drug; group 3 includes 8 cases of severe granulopenia, many with a typical picture of agranulocytic angina, and 4 of which ended fatally.

The authors discuss the relative benefits and dangers of thiouracil therapy as compared with the dangers of thyrotoxicosis and thyroid surgery. They point out that whereas most deaths following thyroidectomy are in patients with severely toxic goiters, thiouracil may cause the death of patients with mild thyrotoxicosis.

In analyzing the possible mechanisms of thiouracil neutropenia, the authors state that marrow biopsies indicate both destruction of mature granulocytes and inhibition of the development of promyelocytes.

Hypersensitivity appears to be the conditioning factor in the production of granulopenia with thiouracil. Thiouracil definitely falls into the group of drugs that produce allergic manifestations—namely, drug fever, urticarial and other types of skin eruptions, and reproductions of toxic symptoms with readministration in small doses."

Thyrotoxicosis seemed not to be a factor in agranulocytosis due to thiouracil since it occurs in the absence, and during remissions, of thyrotoxicosis. Dosage and duration of treatment also seemed to be not important.

Both acetalization and desensitization have been observed.

Patients who receive thiouracil must be under constant supervision. Since the onset of neutropenia and agranulocytosis is not detectable without blood counts, it is recommended that white cell counts be made three times weekly. The authors advocate the following treatment of agranulocytic angina associated with thiouracil: withdrawal of the drug, blood transfusions, and the administration of penicillin, liver extract, pentonucleotide, and yeast.

CARROLL H. THURMAN, M.D.

Lora, J. M.: Stripping of the Vocal Cords. *Arch Otolaryngol.* 1945 42: 378.

Experimental stripping of the vocal cords in cats established the fact of vocal cord regeneration. Application of this operation to the human larynx confirmed the experimental findings.

All types of benign lesions lend themselves to the stripping operation. Hyperkeratotic papilloma can be cured by this operation.

General anesthesia supplemented by local anesthesia induced by the application of a solution of such anesthetic drugs as cocaine hydrochloride or tetracaine hydrochloride is the anesthesia of choice.

The operative technique has proved satisfactory. The postoperative management with silence or the whispered voice is questioned. Better end results have been obtained by permitting reasonable use of the voice. Functional results have been good.

The satisfactory results obtained warrant the continued application of the principles of this operation.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Toinick, B., and Beck, W. C. The Histamine Flare in the Emulsiion of Peripheral Nerve Lesions. *War Med.*, Chic. 1945 8 386

As an adjunct to other objective tests in the diagnosis of peripheral nerve lesions the authors advocate and describe the histamine flare test. The test consists of an intradermal injection of 0.1 c.c. of a 1 to 1,000 solution of histamine phosphate in the affected extremity and as a control test on the unaffected side. The small red reaction it has on injection and the wheal which follows it have no diagnostic importance. The flare comes later and its intensity and dimensions vary. It depends on intact arteriolar circulation and on an intact axon reflex. Thus the presence of a flare will indicate that both the local nerve supply and the local blood supply are present, and the absence of a flare will indicate that either the blood supply is absent or the peripheral nerve supplying the area has undergone degeneration.

From their limited observations the authors suggest that in the absence of a flare the nerve is completely divided and requires early surgical repair. They interpret the appearance of a partial flare as due to a concussion or edema of the nerve, for which recovery will be spontaneous without operative intervention.

The presence of the histamine flare being entirely dependent on the degeneration of the axon, it may also be an objective test in the differentiation between the hysterical and the organic anesthetics. It may also be of value in the differential diagnosis of hysteria and malingering. The injection of histamine is painful and the malingering will almost always give evidences of pain or of pruritus.

GEORGE PERRET, M.D.

BRAIN AND ITS COVERINGS CRANIAL NERVES

Grunnagle, J. F. Early Treatment of Open Head Wounds. *War Med.*, Chic., 1945 8 376

The author's article deals with his experience in the treatment of open head wounds in a general hospital during a period of 7 months in the Philippine campaign. Forty per cent of the patients suffered infections of various types, and the mortality was 1 per cent.

The objectives in the treatment of cranio-cerebral injuries are the preservation of life, the preservation of function and the prevention of infection. The elimination of infection will do much toward the accomplishment of the two other objectives and prevention will depend almost entirely upon the application of sound first aid measures and the early definitive surgical repair.

The first aid measures include, mainly the treatment of shock and the loss of blood, drainage of a distended urinary bladder, the institution of systemic sulfonamide and penicillin therapy, shaving and cleansing of the scalp, the application of a large sterile dressing, the administration of tetanus toxoid, and prompt evacuation of the patient to a hospital equipped for definitive surgical intervention on such wounds.

The optimum time for debridement is within the first 6 hours following injury but it can be done after a longer interval has elapsed if adequate penicillin and sulfonamide therapy have been instituted. Debridement of all involved tissues, and closure of the wound without drainage as the best means of preventing infection. All patients in whom the scalp had been debrided and left open and a sulfonamide dressing had been degrees of infection and closed, with varying degrees of infection and closed, scalp wounds which had been debrided and some of them had been broken down. On the other hand all wounds which had been debrided and closed tightly without drainage had healed with no evidence of infection, which proved the efficacy of that method of treatment. The author believes that the same principles should be applied in the treatment of fractures of the skull. He emphasizes the importance of the removal of all foreign material, fragments and contaminated bone cases in which the dura had been torn showed severe and extensive damage as the result of infected cerebral herniations, meningitis or brain abscess in addition to osteomyelitis of the skull and cellulitis. Neither herniation nor infection occurred in patients in whom early and adequate debridement and closure had been accomplished. The author states that if necessary closure of the dura can be obtained by the use of a graft taken from the sheath of the temporal muscle, pericranium, or fascia lata. The same observations were made following the treatment of more extensive cerebral tissue, bone fragments blood clots, and debris by careful irrigation and suction is allacerated debrided. Closure of the dura, to avoid cerebrospinal fluid (without associated lacerations) recommended. Closure of the primary importance of cerebral pressure was treated by the use of a graft taken from the sheath of the temporal muscle, pericranium, or fascia lata. The same observations were made following the treatment of more extensive cerebral tissue, bone fragments blood clots, and debris by careful irrigation and suction is allacerated debrided. Closure of the dura, to avoid cerebrospinal fluid (without associated lacerations) recommended.

The author believes that penicillin and sulfonamides should be given to all patients with severe

cranio-cerebral injuries, but that the use of these drugs does not replace proper and early surgical débridement and repair. Drains offer a pathway for the entrance of infection and should therefore be avoided. Tight closure of the débrided wound is the best safeguard against infection.

GEORGE FERRIS, M.D.

Wycis, H.: Bilateral Intracranial Section of the Glossopharyngeal Nerve; Report of a Case. *Arch. Near Psychol. Chlc.* 1945, 34: 344.

This brief article gives a concise review of the surgery on the glossopharyngeal nerve and a résumé of the effects of the glossopharyngeal nerve on the carotid sinus mechanism.

A case report is given of a patient who was operated upon with bilateral section of the glossopharyngeal nerve for the pain of carcinoma of the epipharynx. On section of the nerves a dramatic rise in blood pressure, pulse and respiratory rate was noted, whereas previous to operation these figures had been at a normal low level, the carotid sinus had not been sensitive to manipulation, and the electrocardiogram was normal. The pulse and respiratory rate remained high for 3 days, and the hypertension persisted for 4 weeks not reaching the preoperative levels until 5 days prior to the death of the patient, when there were signs of circulatory failure. The patient died of suppurative pneumonitis 1 month after operation due, not to inability to swallow because of the section of the glossopharyngeal nerves, but dysphagia, but rather to a constantly sloughing epipharyngeal mass which discharged continuously into the lower pharynx. In and of itself bilateral section of the glossopharyngeal nerve is compatible with normal life.

JOHN MARTIN, M.D.

Woolf, J. I.: Acute Hypertension with Sodium Pentothal Anesthesia in Neurologic Surgery. *Ann. Surg.* 1945, 124: 1146.

Acute arterial hypertension which occurs during the subtemporal approach to the gasserian ganglion has been reported when sodium pentothal anesthesia is used. This rise in blood pressure is well defined and in a consecutive cases averaged 51.3/38.5 mm. of mercury.

A similar rise in blood pressure did not occur when ether anesthesia was used.

Further studies were conducted upon patients operated upon for herniated intervertebral discs under sodium pentothal anesthesia. No elevation of the blood pressure could be demonstrated.

It was also noted that the final blood pressure was higher in both the dislocated intervertebral disc series as well as the gasserian ganglion series when anesthesia. It was therefore suggested that post-operative shock was less likely to occur under such anesthetics.

It is not possible to give an entirely satisfactory explanation of the acute hypertension noted ex-

clusively in the patients operated upon for section of the sensory root of the gasserian ganglion. It is suggested that there may be a hypersensitivity of the cerebral vasomotor centers under pentothal anesthesia. Retraction of the temporal lobe may result in widespread pressure or irritative effects although the site of vasomotor stimulation is not known.

No untoward effects were noted as the result of this temporary hypertension during surgery.

HOWARD A. BROWN, M.D.

SPINAL CORD AND ITS COVERINGS

Shenkin, H. A., Horn, R. C., Jr., and Grant, F. C.: Lesions of the Spinal Epidural Space Producing Cord Compression. *Arch. Surg.* 1945, 51: 1185.

The authors review the spinal extradural compressive lesions encountered in a 10 year period (1934-1944) in the material of the Laboratory of Neurosurgical Pathology of the Hospital of the University of Pennsylvania. These formed a series of 54 cases and comprised roughly 3 per cent of the total lesions are classified pathologically and described.

Metastatic carcinoma was proved in 9 cases. Of these, 8 patients were over 50 years of age, and 1 (a man with a probable primary kidney tumor) was 27 years of age. Symptoms of root compression appeared first, followed usually after a period of several months, by cord compression. Progression was rapid and the systemic nature of the process was suggested by weight loss. Roentgenograms showed vertebral erosion. In 6 of the 9 cases the primary site of the lesion was never determined. In addition to the kidney tumor primary carcinoma of the lung was discovered in 3 cases. Decompression gave relief of pain but failed to relieve the symptoms of cord compression.

All of the tumors were friable and encased the dura. The laminae and spines were extensively involved. Five of the lesions were adenocarcinomas, 3 were squamous cell epitheliomas, and 3 were undifferentiated.

In 7 patients in the fifth to seventh decades of life, myelomas were found. All patients had symptoms of a sudden onset of cord compression. Roentgenograms showed vertebral erosion and complete spinal subarachnoid block. In one-half of the cases there were symptoms of premonitory root irritation. Complete studies were made in 4 of the cases and in only 1 case was the vertebral lesion shown to be an isolated one. There were no alterations in serum proteins and the presence of Bence Jones protein in the urine was not observed in the 3 cases in which these examinations were carried out.

The epidural mass found at operation was extremely vascular. The tumors were composed of closely packed masses of cells resembling plasma cells. As a group, the patients succumbed rapidly the longest survival being 14 months.

Six cases of neuroblastoma (sympathicoblastomas) were found. Three of the patients were between 9

SURGERY OF THE NERVOUS SYSTEM

and 33 years of age and the remaining 3 were 6 months, 22 years and 67 years of age. The two older patients had had pain for a period of 6 months prior to cord compression, the duration of pain in the other 4 patients had been less than 1 month. Roentgenological evidence of vertebral involvement was noted in 2 cases, a retroperitoneal mass was present in 4 cases and a posterior mediastinal tumor in 1 case. The tumors appeared bluish red and very vascular and tended to infiltrate into the paravertebral muscles. The majority of the tumors were located in the lower dorsal and upper lumbar regions. The six-months-old infant is living 1 year after operation, and has shown some neurological improvement, the other 5 patients are dead.

The histological appearance of the tumors was that of solid cord or small nests of tumor cells separated by delicate fibrous bands. The nuclei were usually stained with scanty cytoplasm. Silver stains showed delicate reticulin fibrils. Some of the tumors showed larger cells with nuclei containing clumps of chromatin. These were thought to be sympathoblasts as described by Ris and Geschickter. In 1 case the tumor may have been primary in bone. In the other cases it seemed to have invaded the epidural space from the retroperitoneal space or the posterior mediastinum.

In 3 patients, giant cell tumor of the bone occurred during the second decade of life. All 3 had root first as the first symptom, followed after a period of several months by the abrupt onset of cord compression with rapid progression of symptoms. All lesions were in the midthoracic region, and roentgenograms showed bony erosion. There was no history of trauma. At operation the authors found an encapsulated tumor mass usually not connected with bone. All 3 patients are well after surgical curettage and postoperative irradiation after 2, 3 1/2 and 9 years respectively. The tumors were composed of giant cells scattered in a vascular and cellular stroma. These cells were of the same type as those seen in giant cell tumors of the bone. The sections of 1 of the lesions showed extensive new bone formation. In the group of lymphosarcoma occurring in the group of miscellaneous neoplasms as their first symptom. In both cases the gross and histological appearance of the tumors were characteristic. In 10 and 10 months after operation, followed by intensive irradiation, both patients are in good general condition and able to get about with the aid of canes.

One case of lipoma in a 45 year old patient, and 1 case of liposarcoma in a 48 year old patient are reported. In the former there was a slowly progressive paraparesis with no symptoms or signs of root involvement, and surgical decompression was followed by complete recovery. In the latter root pain for 1 month was followed by complete paraplegia which developed in 24 hours. At operation a red beefy

mass involving the eighth thoracic vertebra was found. The patient was unimproved by operation.

An encapsulated hemangioma caused progressive weakness in a 54 year old woman. This was completely removed and the patient made a full recovery. Another blood vessel tumor a malignant hemangiopericytoma metastasized to the epidural space from the thigh in a 43 year old man. His symptoms were not relieved by operation and death occurred after a period of 5 months.

In a case of acute monocytic leucemia in an 18 year old girl leucemic infiltration caused root pain and rapidly progressive quadriplegia. Death occurred on the ninth day after operation. One completely extradural neurilemmoma was found in a 52 year old woman who had had symptoms of cord compression and root pain for a period of 7 months. At operation the tumor was only partially removed and the patient had a recurrence of several months however, there was a recurrence of the tumor and the patient finally succumbed to sepsis.

There were 2 unclassified tumors one of which closely resembled a hemangioma, the other a malignant neurilemmoma. In 2 of the patients in this series spinal extradural cysts were present. These were characterized by aplastic paraparesis and loss of position and vibration senses in the legs. Roentgenograms showed a uniform erosion of the pedicles. Following operation removal of the cysts both patients made complete recoveries.

Chronic epidural hematoma caused cord compression in 2 patients. Neither of these patients had any history of trauma, and the onset of symptoms was very sudden. At operation the lesions appeared similar to those of an intracranial subdural hematoma. Following decompression 1 patient was completely well the condition of the other patient was unimproved. There was 1 case of acute epidural hemorrhage following trauma. This patient was not benefited by operation.

There were 6 cases of acute epidural abscess. The onset of symptoms was sudden and the progression rapid in all cases. The source of the infection and the organism (hemolytic staphylococcus albus) were easily determined. The abscesses were very extensive and only 1 patient was benefited by operation. Two patients with tuberculous granuloma were operated upon. In each of these the indications for operation were symptoms of cord compression since tuberculosis was not proved until after operation. A diagnosis of tuberculosis usually contraindicates laminectomy.

Three cases of syphilitic gumma of the epidural space were observed. The Wassermann reaction of both the spinal fluid and the blood of all patients was positive. Except for root pain and cord compression caused by the gummas, these patients were free of symptoms of syphilis. All were given antiluetic therapy postoperatively and all were completely relieved of symptoms.

The authors series also includes 3 cases of non-specific granuloma. The symptoms were slowly progressive in all of the patients. Only 1 of the 3 was benefited by operation. ROBERT E. GREEN, M.D.

MISCELLANEOUS

Walker, A. E., and Johnson, H. C.: Principles and Practice of Penicillin Therapy in Diseases of the Nervous System. *Ann. Surg.* 1945, 2 1185

Although systemic penicillin appears in the spinal fluid in only minute quantities when injected into a normal animal or person, the amounts are materially increased and will be sufficient to cause bacteriostasis for the more sensitive organisms when meningeal irritation, caused either by sterile media (such as air in pneumoencephalography) or by bacterial invasion, is present.

In intrathecal administration of the drug, the best diffusion and the highest levels are found in intraventricular injection. Injection into the cisterna magna gives the next best results and injection into the lumbar subarachnoid space the poorest. Both of the former routes are too dangerous for any but very extraordinary cases.

Intrathecal penicillin can produce toxic effects on the nervous system. Twenty thousand units in 1 c.c. of saline injected into an experimental monkey produces transient perianal paresthesias, and in some cases convulsions, coma, and death. A patient who was given 100,000 units of penicillin in 5 c.c. of saline developed urinary retention, saddle paresthesias, and paraparesis. It required 3 months for these symptoms to clear up. Neymann has re-

ported 2 cases of convulsions, coma, and death when 50,000 units of penicillin were injected into the cisterna magna of patients with dementia paralytica. Convulsive manifestations are more likely to follow intraventricular injection of the drug, or its topical application to the cerebral cortex.

In the treatment of specific disease, penicillin should not be used for meningococcus meningitis unless sulfadiazine fails to yield improvement in from 24 to 48 hours. In this disease, intramuscular penicillin (40,000 units every 3 hours) should be used.

For streptococcal meningitis, intrathecal as well as systemic infection is required. This is also the case for staphylococcal meningitis.

In the treatment of pneumococcal meningitis, a disease that was uniformly fatal before the advent of chemotherapy, sulfadiazine plus both systemic and intrathecal penicillin should be used.

In the surgical treatment of compound fractures of the skull, from 5,000 to 20,000 units of either dry or aqueous penicillin may be placed in the wound in addition, systemic penicillin should be given.

Before a brain abscess is drained, systemic penicillin (100,000 to 300,000 units) should be given daily. At the time of drainage 1,000 to 20,000 units may be instilled into the cavity.

Infected meningococci and meningomyelococci respond well to penicillin therapy.

Penicillin has a favorable effect on early neurosyphilis, but tuberculous meningitis, brain tumor, multiple sclerosis, amyotrophic lateral sclerosis, and cerebral degeneration are unimproved by the drug.

ROBERT E. GREEN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Govan A. D. T.: Two Cases of Mixed Malignant Tumor of the Breast. *J. Path. Bact., Lond.*, 1945, 57: 597

The following 2 cases of mixed malignant tumor of the breast were reported not only because of the rarity of these growths but also because the histological diagnosis appears to be unusually precise and the similarity of the case histories and subsequent development makes them of clinical interest.

The patients were admitted to the Queen Elizabeth Hospital, Birmingham, England. Their ages were 37 and 47 respectively. They both complained of a progressive swelling of the breast which developed a discharge from the nipple. Examination revealed an enlarged nodular (cystic) breast which was mobile. No other pathological conditions were elicited.

No other patient was treated by excision of the breast. One patient was treated by deep x-ray therapy. The other was followed by a mastectomy followed by x-ray therapy. Both patients made an uneventful postoperative recovery and were discharged to the hospital shortly after their discharge, the first patient complaining of a lump in the axilla and the second of a lump in the incision. The patients received further surgical and x-ray therapy. Death occurred a few months later. Secondary metastases to the lungs and spine were found.

Laboratory examination revealed the growth to be well circumscribed and in parts almost encapsulated. It could be divided roughly into cystic and noncystic parts which gave the tumor an irregular lobulated appearance. The cysts were formed by hemorrhagic. They might well have been formed by necrosis of and hemorrhage into parts of the tumor. The neoplastic tissue consisted of solid white, fleshy masses bearing little resemblance to the usual carcinoma growths of this region. There was no suggestion of irregular or widespread infiltration of the normal tissue such as one finds in carcinoma. At all points the growth was clearly demarcated from the normal breast tissue.

It was at once evident on microscopic examination that two types of growth, carcinomatous and sarcomatous, were present. The carcinoma could be seen to have originated in the main ducts. It was absent from the tissue surrounding the hemorrhagic cysts and from the lobulated masses at the periphery. Here and there smaller and more irregular islands of carcinoma could be seen in the central portion but always well defined and clearly differentiated from the second type of growth.

It must remain in doubt whether the sarcoma or the carcinoma was the cause of the metastases which were undoubtedly present. There was, however, no evidence of lymphatic permeation and the subse-

quent history is one of early local recurrence with later metastases to the lungs and bones via the blood stream. These facts would suggest that it was the sarcoma which had disseminated, and indeed it would seem unlikely that a well differentiated carcinoma with relatively few mitoses, would produce blood borne metastases in such a short time.

The sarcoma cells were derived from the muscle the majority of cells were spindle. Numerous giant cells also were present.

In general the growths were not vascular and little stroma could be demonstrated by ordinary methods but silver impregnation revealed an abundant reticulum which closely invested the individual cells of the sarcomatous portion.

LEE PULLEN M.D.

TRACHEA, LUNGS, AND PLEURA

Blackburn G., and D'Aren A. L.: Thoracoabdominal Wounds in War. *Br J Surg* 1945 33: 153

The authors analyze 126 cases of thoracoabdominal wounds treated at forward operating centers and 74 cases treated in the surgical division of a base hospital. Of the 126 patients treated at forward operating centers 46 (36.5%) died of the 74 patients who reached the base hospital, only 3 died.

The distinction between thoracoabdominal wounds and abdominothoracic wounds is important. The great majority of wounds belong to the first group the wound of entry is in the chest, and the foreign body or the wound of exit is below the diaphragm. The thoracoabdominal wounds respond more favorably than those of the opposite type, and are less likely to require laparotomy. Wounds of the right side tend especially to belong in this category and if the liver is the sole abdominal viscus that is injured a laparotomy need not and should not be undertaken. Only 8 of 65 right sided wounds had an associated hollow viscus lesion while 30 of 61 left sided wounds had hollow viscus lesions, with a correspondingly greater mortality among the patients with left-sided wounds. The authors believe that laparotomy should be avoided if possible. If how ever a laparotomy is necessary a Kocher's incision will give excellent access. The type of thoracic operation also is subject to variation most British surgeons being content with rib resection and closure of the pleura after repair of the thoracoabdominal injury has a place, especially for wounds on the right side, but certainty of diagnosis is difficult without radiography. A wound may be labelled thoracoabdominal only when (1) a foreign body with an entry wound in the chest, can be demonstrated below the diaphragm (2) hematuria is combined with hemothorax or hemopneumothorax (3) the presence of

INTERNATIONAL ABSTRACT OF SURGERY

pleurobiliary fistula is proved by thoracic paracentesis.

Although the mortality rate in those patients who survive the initial wounding and operative treatment is low the morbidity rate is high.

The complications in the series of 74 cases were as follows:

Hemothorax, 38 cases atelectasis, 15 cases subphrenic abscess 12 cases (6 with coincident empyema), empyema 11 cases empyema with pleurobiliary fistula 7 cases lung abscess, 3 cases and liver abscess, 2 cases.

The management of hemothorax is no different from that in a simple thoracic wound. Re-expansion of atelectatic lobes after postural drainage and breathing exercises is the rule and a course of sulfadiazine is often of value in reducing pyrexia where progress is slow. Both lung abscesses recorded in the table resolved without operation, but were treated with a course of parenteral penicillin.

The most significant complication is empyema. All cases of empyema are not due to infection of the hemothorax, since a considerable number follow a lower lobe collapse associated with serous effusions that become purulent. It is essential, therefore, to watch for signs of effusion constantly and to perform paracentesis thoracis if clinical or radiological signs develop. The diagnosis of pleurobiliary fistula is easily made by examination of fluid obtained by aspiration from the pleural cavity. Drainage should be instituted early, as loculation is likely if drainage is delayed. Significant diagnostic features of subphrenic abscess were hectic fever with its constitutional malaise, high leucocytosis, local tenderness and swelling, restricted rib movements, a diaphragm invisible radiologically with a fluid level beneath it and an overlying sympathetic pleural effusion. Diaphragmatic hernia is uncommon as a sequel of thoracoabdominal wounds.

The causative missile is rarely seen during operation for thoracoabdominal injuries but should be removed if easily accessible. In cases with retained foreign bodies, the liver is a common site, but the late of retained missiles in the liver is difficult to ascertain. It may be wishful thinking to suggest that they do not often cause mischief. A case of fatal abscess occurring in the liver after removal of a foreign body is reported.

JOHN L. LINDQUIST, M.D.

ESOPHAGUS AND MEDIASTINUM

Nielsen, J.: Clinical Results with Rotation Therapy in Cancer of the Esophagus. *Acta radiol.* Stockholm, 1945 26: 361.

Rotation therapy offers some fresh possibilities in dealing with cancer of the esophagus which has hitherto proved little amenable to curative treatment. The author's report is based on results obtained with the rotation method of treatment in the past 3 years. The clinical development of carcinoma of the esophagus (the most malignant and most

rapidly lethal form and site of epithelial cancer) has hitherto been so quickly fatal that it is permissible already after a relatively short period of observation, to draw certain conclusions with regard to the therapeutic effect.

Experimental studies and measurements on phantoms revealed that the most favorable degree of effect is obtained when the focus skin and the half size of the field and the object, and when the latter are as small as possible. With the use of 180 kilovolts 0.5 mm. of copper and 15 milliamperes, the intensity measured in air is 65 r/min. at a distance of 40 cm., and 42 r/min. at a distance of 50 cm. Each sitting can thus be given in a reasonably short period of time (10 to 15 minutes).

The material was comprised wholly of referred cases. No case was refused, not even at the preliminary examination. A considerable proportion of the patients were severely affected and much encumbered with metastases to the lymph nodes in the neck, and the liver, the lungs, and the bones.

One hundred and ninety-four patients were treated by irradiation. Of these, 174 (90%) were given rotation therapy. Eight patients (4%) were so feeble upon admission that no treatment could be given. Twelve patients (6%) in whom the cancer was situated in the cervical part of the esophagus (most of these were women), or at the level of the jugulum (a not uncommon site in men) were given crossfire irradiation to multiple fixed fields but the author believes that the rotatory treatment will always have the advantage, essentially over crossfire irradiation through fixed fields by increasing the depth dose rendering the focal dose homogeneous, and eliminating the risk of over-crossing effects.

The screening control requires that the patient shall be seated on a stool which during irradiation rotates about a vertical axis, while the roentgen tube is fixed in a position with the central ray directed horizontally. Only slight cutaneous reactions were observed, and in spite of large daily and total doses, there were no general reactions except moderate leucopenia nor were there any other unpleasant after symptoms. The total dose, which is reached in the course of 5 to 6 weeks (sometimes 7 to 8 weeks and a minimum of 3 weeks) is about 5,000 roentgens.

The roentgenological diagnosis of tumor in all the cases was verified by microscopy in 113 (60%) squamocellular carcinomas of the esophagus, which constitute the majority of the carcinomas in that site, are not as highly differentiated as for instance, carcinomas of the tongue and oral cavity and would indicate a correspondingly greater radiosensitivity. There is, therefore reason to contest the not uncommon belief that nearly all carcinomas of the esophagus are, histologically of a strongly keratinizing squamocellular type, and consequently radioresistant. When the question is of squamocellular carcinomas, which on account of their comparatively slight

SURGERY OF THE THORAX

radiosensitivity require a considerable amount of daily radiation, the reaction of the tumor will be all the greater the shorter the full treatment time can be made in other words the higher single and daily doses can be given. If the treatment is extended over too long a period there is time for the development of connective tissue reactions with the result that not all the cancer cells become destroyed.

In 117 cases (four fifths of those fully treated and two-thirds of the total number) complete or nearly complete primary freedom from symptoms was obtained that is almost normal deglutition and roentgenologically marked improvement of the esophagus. The improvement of the deglutition was of shorter or longer duration. Recurrences in the esophagus were not infrequent they often occurred above or below the primary stenosis and were then accessible to another palliative irradiation. In many cases the patient was able to swallow right up to the time of death which in most cases was due to metastases or cachexia. The results so far show an indubitable improvement of the survival curve.

LEE PULLEN M.D.

MISCELLANEOUS

Wood, H., and Sweetser H. B. Jr.: Punctate Cerebral Hemorrhage following Thoracic Trauma
U S Nav M Bull., 1946 46 57

On the authors hospital ship 3 fatalities were encountered from symmetrical diffuse, punctate cerebral hemorrhage secondary to severe thoracic trauma and multiple fractures. The first case carried a diagnosis of atmospheric blast concussion the second resulted from a fall. Histological study of the 3 cases revealed hardly any cerebral fat embolism as a basis for the punctate cerebral hemorrhages.

The first patient, injured by an atmospheric blast had an extensive right thoracic and abdominal contusion, right hemothorax, puncture of the right lung one fractured right rib a fracture of the humerus and right acetabulum rupture of the spleen and liver hematoma of the right adrenal gland, renal bleeding mediastinal hemorrhage, and hemorrhages into the serous membranes of the thoracic and abdominal cavities.

The second patient was injured by a fall from a height of 25 feet, which resulted in an extensive

right thoracic contusion fracture of 6 right ribs, right hemothorax and atelectasis (with terminal acute lobular pneumonias) puncture of the right diaphragm and the liver, and hemorrhages into the serous membranes of the pleural and abdominal cavities. Each case was characterized clinically by progressive coma with no localizing neurological signs.

Both patients showed pulmonary fat embolism. The first case in which there was fracture of the long bones was much more extensive than the second. A fat embolus was demonstrated in a capillary of the cerebral white matter in the patient cited in case 1 but it was not associated with hemorrhage. No fat embolism was demonstrated in the cerebral white matter of the patient in case 2.

The hypothesis is presented that the force of the trauma to the thorax of these patients was transmitted to the venous circulation and resulted in a retrograde wave of elevated venous pressure. The degree of force involved in these cases was sufficient to overcome the barrier of the one set of venous valves located near the termination of each internal jugular vein. From that level to the capillaries of the brain there are two direct, relatively short columns of blood which are unprotected by venous valves.

The most abrupt change in vessel caliber is from the capillaries of the cerebral white matter and the basal nuclei to the great cerebral vein. The venous tract from the capillaries of the cerebral white matter basal nuclei and upper midbrain to the confluence of the dural sinuses is more direct, and is generally shorter than the tract from the capillaries of the cerebral cortex to the confluence of the sinuses. The angles at which the superior cerebral veins enter the superior sagittal sinus and the presence of the folds of dura in relation to the ostia of these veins would tend to lend protection to the capillaries of the cortex from a retrograde wave of pressure.

In brief a retrograde wave of venous pressure should strike the capillaries and venules of the cerebral white matter before it strikes those of the cerebral cortex. The force should be less readily dispersed in the white matter than in the cortex. This hypothesis should be subjected to experimental study.

LYNN JOHNSON M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Chandy, J.: The Use of Heterogenous Fascial Grafts in the Radical Operation for Hernias. *Ann. Surg.* 1945, 835

The author apparently prepares his own deep fascia of an ox or cow and uses white cotton No. 40 for sewing the flap of fascia to protect the floor of the inguinal canal.

The preserved ox fascia, which measures about 5 by 15 inches is dried of alcohol between gauze and placed on the area. One long border of the fascial graft is sutured to Poupart's ligament by 4 interrupted sutures. The lower corner is sutured to Cooper's ligament and the inferior border is fastened to the periosteum of the pubic bone taking care to include a good part of the periosteum. A slit about one half inch in length is made on the upper border of the graft, and the cord is passed through this opening. A suture is passed through the *fals inguinalis* while the muscle is being lifted by a retractor, continued through both corners of the slit and tied. The fascial graft is thus anchored under the *fals inguinalis* with allowance for passage of the cord. Two sutures are used to anchor the fascia under the conjoined tendon, and 3 to secure the fascia under the rectus sheath on the medial side. Sometimes it may be necessary to slit a part of the rectus sheath to insert the fascial graft under that ligament. Now the fascia is well anchored to Poupart's *fals inguinalis* and rectus sheath, and under and to the through a narrow slit in the fascia.

The cut edges of the external oblique aponeurosis are next sutured and the wound is closed by interrupted sutures.

The work of Hays on the use of preserved ox fascia in the living dog has been extended to patients. Especially prepared ox fascia appears to heal solidly in human tissue.

Experience with 158 cases, and follow up observations on a series of 53 employees of a firm providing routine medical examinations at monthly intervals, are presented. There were no recurrences in the latter group after periods of observation ranging from 10 months to 4 years and no recurrences were reported in the remaining 105 patients.

JOSEPH GARTER, M.D.

GASTROINTESTINAL TRACT

Somervell T. H. Physiological Gastrectomy. *Bull. J. Surg.* 1945, 33, 46.

The author has been replacing the extensive operation of partial gastrectomy by the more modest procedure of ligating the arterial supply of the stomach with good immediate results. The opera-

tion of vascular ligature has been done in 400 cases, 160 of which have been studied by test meals before, and 3 weeks after operation, and 82 of which have had a late follow-up including the performance of fractional test meal and a thorough clinical examination. In 380 cases of arterial ligature with or without gastroenterostomy only 1 death could be traced. The minimal operative risk and satisfactory results of the simpler operation are believed to give which the total acidity of the fasting juice is above 60, gastroenterostomy combined with ligation of the arterial supply of the stomach is carried out, except in the cases of patients with gastric ulcer as well as a duodenal ulcer or those in whom malignancy is suspected.

The operation of tying the arteries in its simplest form, consists of firmly ligating with fine silk about 5 of every 6 of the small branches which run from the gastrophlopic artery to the stomach wall as far up the greater curvature as possible without pulling at the stomach. The sheaf of vessels on the lesser curvature is ligated *in toto*. The arteries at the pylorus and within an inch of it need not be tied. The posterior wall of the stomach is then greatly pulled through the opening in the mesocolon and it is usually found that further ligations must be done to bring the number of ligated vessels up to approximately five-sixths of the total number. Gastrojejunostomy is then performed.

When the arteries are tied in this way the usual effect is an immediate and considerable drop in the acidity of the stomach. A hyperacid stomach becomes one which secretes less than the normal amount of acid. Control studies were made by testing pre- and postoperative acidities in cases of arterial ligature without gastroenterostomy and in cases of gastroenterostomy without arterial ligature. The results of these studies indicate that the reduction of acidity is due to the ligation of the arteries and not to the gastroenterostomy.

Fractional test meals were done in 82 cases from 6 months to 6 years after operation. It was found that the lowering of acidity persists for at least 3 years and the late results showed very satisfactory figures both for the acidity of the fasting juice and for the average total acidity during the 3 hours or so after the meal was given. In cases in which the operation of arterial ligature alone was done, without gastroenterostomy, the early and late results were exactly similar to those in which arterial ligature and gastroenterostomy were combined. With regard to the incidence of recurrent (gastrojejunal) ulcer of the total number of 400 patients in whom this operation has been done, only 2 has returned to the hospital with a gastrojejunal ulcer. This is in contrast to the incidence of 7 cases of recurrent ulcer in a series of 300 cases in which a gastrectomy

had been done during the same period. It is believed that arterial ligation is the operation of choice in all cases of duodenal ulcer with marked hyperacidity.

JOHN L. LONGQUEST M.D.

Oleson, O.: Multiple Cancer of the Colon (Cancer collimultiplex). *Acta radiol. Stockh.* 1945 26 415

The paucity of clinically diagnosed multiple carcinomas of the colon as compared with the figures from the autopsy room suggests of course that many cases of multiple cancer of this region are not being diagnosed. This is of interest to the roentgenologist, who must not rest content with having established the diagnosis of a cancer of the large bowel but should continue his examination to include the entire colon. Even though the referring surgeon be satisfied with the digital or proctoscopic findings of carcinoma of the rectum, in view of the especial frequency of the combination of rectal cancer with a second cancer in another section of the colon (this combination being found in perhaps a half of all the cases of multiple tumors of the large gut), a complete examination of the entire colon should be made since the tumor which is overlooked in these cases may eventuate seriously.

The surgeon who refers his patient to the roentgenologist frequently merely wants the determination of the upper limits of the tumor which he already knows to be present or he wants to know the length of the sigmoid for the technical operative value of such determination. He may even oppose the filling of the entire bowel with the shadow producing medium. The roentgenologist, however, should not limit his quest for considerations such as these. Of course, the entire colon should not be burdened with the medium when an acute ileus is present, or in the presence of an almost impervious stenosis of the bowel lumen. However in the latter case too much importance should not be attached to the fact that the inflowing of the contrast material in retrograde direction is difficult.

In making the decision to break off the examination short of the entire length of the colon the preliminary roentgenogram without contrast substance should be carefully studied particularly in the presence of acute ileus or when there has been a history of attacks of acute or subacute ileus in order to estimate if the succeeding contrast roentgenogram sufficiently explains the history symptoms and present findings. If then for any reason the examination remains a partial one the surgeon should of course be apprised of the fact that the examination is incomplete. According to Crawford (*Acta chir scand.* 1934, 74) not less than 65 per cent of his 161 patients with an obstruction presented stenoses.

The author appends 5 case histories of multiple cancer of the colon—the rectum and anal sections are included as part of the colon—from a year's material of from 50 to 60 cancers of the colon and from 700 to 800 examinations. In only 1 of these did the roentgenologist fail to uncover the multiplicity of the condition.

JOHN W. BRENNAN M.D.

Jenkins, J. A.: Carcinoma of the Rectum, with Special Reference to Sphincteric Control. *Austral. N. Zealand J. Surg.* 1945 15 15

Radical operation for carcinoma of the rectum must continue to be the method of choice in the majority of cases for which surgery is employed. A brief description of the procedure adopted in cases in which the sphincteric mechanism can not be saved is presented. The author prefers a two stage operation.

The first stage involves exploration through a left oblique abdominal incision to determine the extent of the growth and fixity. If conservative preservation of the sphincters is decided upon a transverse defunctioning colostomy is done. If a radical perineoabdominal excision of the rectum is not contraindicated a terminal colostomy is performed. The pelvic colon is exteriorized and divided the proximal stump, held by forceps, is retained in the upper angle of the wound and the lateral peritoneal passage is closed by suture the distal stump is closed and intussuscepted into itself as far as possible and placed in the pelvis. The abdomen is then closed.

The second stage is carried out about 3 weeks after the first stage. The perineal part of the operation is done first and completed abdominally. A vaseline gauze pack is introduced into the pelvic cavity and commencing about the tenth day is gradually removed. A catheter and tidal drainage prevent the threatening bladder infection.

The author presents case histories and reports his observations with regard to the various conservative surgical procedures attempted, in which the sphincteric mechanism is retained. He cites the literature dealing with various conservative procedures and the indications for their adoption in selected cases. Pathologically various reports have modified the earlier hypothesis of the manner of spread of carcinoma of the rectum based on the work of Miles. For example, Pannett states that the rectum can be safely incised 15 cm. below the tumor and 25 cm. above. Functional results are mentioned by most writers and all appear to be reasonably satisfied with the control achieved. However Kirschner states that even after perfect healing complete continence is rarely achieved because of unavoidable damage to the sphincter and to the nerves of the sacral plexus supplying it.

The author suggests a preliminary defunctioning transverse colostomy when conservative procedures are to be followed. A wider sacral exposure with consequent avoidance of splitting the posterior vaginal wall is suggested. The anorectal sphincteric ring is retained intact, as far as musculature is concerned to avoid loss of function. The author believes that after resection of the rectum the patient must depend upon external sphincters for control, and that this control is inadequate when compared to the normal mechanism. No reference could be found in the literature as to the state of the internal sphincter muscle after operation however it is sup-

posed that the intrinsic nerve supply must be abolished. The normal reflex changes which influence the tone of the internal sphincter become inoperative thereby a loss of defecation reflexes occur. There is no doubt that the involuntary non-striated internal sphincter is important in the control of the anal sphincteric mechanism and that it possesses a continuous postural tone that varies slowly in response to reflexes from the bowel above. Although the condition of the internal sphincter has not been established after resection of the rectum, it has been thought that its tone was dependent upon the integrity of a local nerve plexus and therefore, theoretically it is possible of recovery following injury.

Since the external sphincter plays an important part in voluntary and reflex responses to effort and in temporary control its retention with its nerve supply is advisable. Impulses from the pelvic colon may give the patient warning of imminent action of the bowels and this action may be temporarily restrained by voluntary contraction of the sphincter and externus.

The Hochenberg pull-through operation gives the most satisfactory results in conservative surgery of the rectum in which the sphincteric mechanism is preserved.

JOHN E. KARASH, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Robertson, H. E., and Ferguson, W. J. The Diverticula (Luschka's Crypts) of the Gall Bladder. *Arch. Path., Chic.*, 1945 43: 2.

The peculiar outpouchings of the mucosa of the gall bladder known as Luschka's crypts, have been so frequently described that there would appear to be nothing important that could be added to the knowledge of their morphology, pathogenesis, or complications. However a closer study reveals so many misconceptions concerning them that an attempt to clarify their anatomic and pathological significance is fully justified.

The gall bladders studied were from two sources: 175 from postmortem examinations and 320 from surgical operations. The authors' special endeavor was to identify crypts in various normal and pathological gall bladders. Examinations were made of a sufficient portion from each specimen to afford a fairly accurate picture of the relative number and depth of the crypts that were actually present.

Among the 175 gall bladders from postmortem examinations, 112 were judged to be grossly and microscopically normal. The term "normal" is used to imply the absence of identifiable signs of any pathological condition that could influence the functions of the gall bladder materially or could contribute clinical phenomena of disease. Of the 112 gall bladders, 65 (58 per cent) apparently contained no diverticula. Thirty-eight of the remaining 47 normal gall bladders revealed diverticula, grade 1 and only 9 could be graded 2 or 3. The conclusion

appears justifiable that anatomically normal gall bladders contain few diverticula and they tend to remain superficially located.

The 320 gall bladders that were removed by surgical operation were from patients who presumably had definite signs or symptoms of gall bladder disease. At any rate the proportion of those gall bladders that contained no diverticula was distinctly less than that of normal gall bladders removed at postmortem examination.

The extensive review of the data furnished by the work of others and of the results of the authors' investigations gives a perspective which appears to represent a logical solution of the several problems with which the literature has been engaged for the past 100 years or more.

The following conclusions were drawn:

1. In approximately half of all gall bladders removed from persons of more than 30 years of age the mucosa has invaginated the underlying structures, sometimes as far as the peritoneal lining.

2. This invagination tends to form diverticular spaces with branching pouches which occasionally simulate mucous glands. They are lined with epithelium corresponding in every respect to that which lines the mucosa of the inner surface of the gall bladder. These cells secrete mucus or a mucouslike fluid.

3. The greater number of the diverticula open into the gall bladder lumen by ducts, which are often tortuous and narrow. Some are cut off in whole or in part from the lumen and become cysts with budlike branches. When such a group is more or less localized, a formation, often called an adenoma, is produced. This is most frequently found in the folds of the gall bladder but may occasionally involve more, or even all of the gall bladder wall. The term adenoma is misleading and inapplicable.

Multicystic or multilocular cystic diverticula are more fitting designations.

4. The crypts thus formed may contain bile, bile pigments, cholesterol crystals or at times, typical biliary calculi. Exudative inflammation may occur in them up to the stage of abscess formation and even of rupture into the peritoneal cavity. The mechanism of such inflammation may be obliteration of the epithelial lining, proliferation of connective tissue and collections of lymphocytes and other cells.

5. Increased intracystic pressure, absence of a muscularis mucosae, a loosely irregularly arranged muscular layer and the independent response of the muscle bundles to physiological stimuli account for the initial diverticularlike indentations. The increased pressure is, more logically, the result of neurogenic dysfunctional states of the extrabiliary biliary system although other mechanical factors such as stones and inflammatory obstructions may play etiological roles.

6. Except for the complexity of the branches, these crypts correspond in every other respect to the so-called false diverticula of the colon and urinary bladder: they are "diverticula of the gall bladder."

7 There is little justification except custom, for calling them Luschka's crypts or Rokitsansky Aschoff sinuses. Not only did these investigators not possess sufficient priority but they failed in several important details to recognize the true significance of the structures that they described.

Maacheroni H. A., Roussi, C. and Boucau E. F.: Internal Biliary Fistulas (Las fistulas biliares internas) *Presna med argen* 1945 38 1397

Internal biliary fistulas may communicate with a pregnant uterus, ovarian cysts, the pericardium, urethra, or the pleural cavity. However in the majority of cases the fistula communicates with the duodenum, stomach, colon, or small intestine. According to one set of statistics 67 internal biliary fistulas were found among 30,000 autopsies. Puestow encountered internal fistulas in 1.2 per cent of his patients with cholecystitis.

The main cause of internal fistula is cholelithiasis or a cancer of the gall bladder. Less frequent causes are abscess of the gall bladder and echinococcus cysts. As to the pathogenesis, pressure by a calculus causes an ulceration of the mucosa, which leads to perivescitis and the formation of adhesions, necrosis, and, ultimately, a fistula. Periduodenitis as a sequel of duodenal ulcer may also lead to the establishment of a communication between the gall bladder and duodenum either directly or through a fistula resulting from an abscess between both organs. A cancer of the gall bladder may invade the adjacent tissues and form fistulas leading to the colon in a great number of cases.

No pathognomonic signs are characteristic of an acute internal biliary fistula. Puestow states that suspicion of an internal fistula is justified in patients with a hepatic colic accompanied by chills, fever, and jaundice, especially if such symptoms are frequent, persistent, or progressive.

In chronic forms dyspepsia may be the only symptom with nausea, vomiting, and pains following errors in the diet.

Röntgenological studies are of great diagnostic value. The opaque medium may be introduced through a duodenal tube. X-ray pictures should be taken in various positions such as the supine, prone, right lateral, and Trendelenburg. The presence of gas in the biliary ducts is a rarity, but, if detected, it points to the existence of an internal fistula of the bile tract.

Involvement of the liver is a grave complication found most frequently in fistulas leading to the colon. Inasmuch as the prognosis of an internal biliary fistula is always grave, surgical intervention should not be delayed although the operative mortality is relatively high, reaching 70 per cent. Especially in acute forms a delay makes the prognosis poor. The fact that bile may be aspirated through a duodenal tube is of no diagnostic value and does not suggest any special time for the surgical intervention.

Persistent jaundice and the presence of white bile in the duodenal contents indicates hepatitis.

The author reports 3 cases of internal biliary fistula.

JOSEPH K. NARAT, M.D.

Itolz, O. A.: Tumors of the Pancreas (Tumores de pancreas) *Arch Soc argen anal*, 1944, 6 451

The author offers the following classification of tumors of the pancreas:

A. Primary tumors: (1) benign unilocular or multilocular cyst, cystadenoma, solid tumor, insular adenoma, angiomatous tumor, and ampullary tumor; (2) malignant: epithelioma of the head of the pancreas, epithelioma of the body or the tail of the pancreas, cystadenoma, carcinoma, malignant insular tumor, malignant ampullary tumor, and sarcoma of the pancreas.

B. Metastatic tumors with primary neoplasm located in the stomach, spleen, left kidney, small intestine, or lymph glands.

Adenoma and malignant insular tumor produce identical symptoms.

Cystadenoma and cystadenocarcinoma have the same macroscopic aspect and only the histological examination will lead to the correct diagnosis. The differentiation of ampullary tumors of the pancreas and neoplasms originating in the lower portion of the common duct offers great difficulties.

If hydatidiform cysts, pseudocysts, and dermoids are excluded, pancreatic cysts may be divided into two groups: congenital and retention cysts.

Cancer of the pancreas forms from 1 to 2 per cent of all cancers found at autopsies. Metastases appear in relatively early stages and are found in three groups of lymph glands: subpyloric, mesenteric, and splenic. A fourth group of minor importance is found behind the pancreatic glands.

From the histological point of view, 4 types of cancer of the pancreas may be distinguished: papillary cystic carcinoma, adenocarcinoma, the medullary type, and epithelioma formed by independent cells disseminated throughout the abundant stroma. The last two mentioned forms probably derive from acini.

Sarcoma of the pancreas is extremely rare.

JOSEPH K. NARAT, M.D.

Radlke, J. C., and Rivero, E.: Statistical Studies of 53 Cases of Tumors of the Pancreas (Estudio estadístico sobre tumores y tres casos de tumores de pancreas) *Arch. Soc argen anal*, 1944, 6 489

Of 53 tumors of the pancreas observed by the authors, 49 were primary and 4, secondary formations. 39 were found in men and 15 in women. Two-thirds of the tumors were found in patients between 50 and 60 years of age. The great majority of the patients were laborers. The largest number of tumors were located in the head of the pancreas, to be followed by that of neoplasms in the tail and the body. Married people predominated in the material observed by the authors.

In numerous instances the diagnostic difficulties were great and cancer of the liver, tuberculosis, blood cysts of the pancreas, tumors of the mesocolon

and cancer of the biliary tract were considered. Among clinical symptoms pain occupied the main place. Jaundice, colic of the hepatic type, a sensation of fullness, nausea, biliary vomiting, icterus, and hematemesis were less frequently observed.

Among complications the following were recorded: obstruction of the biliary ducts, ascites, liver cirrhosis, fat necrosis, brown atrophy of the myocardium and pneumonia.

The most frequent type of tumors was cancer. The malignant degeneration was accompanied by 3 histological changes: fibrosis, acidophilic necrosis, and flattening of the acini. The authors confirm the observation made by other writers that glandular acini undergo rapid destruction by the cancerous tissue while the Langerhans islets show attempts at regeneration. In 4 cases an association of the cancer of the pancreas with diabetes was observed. In 1 case the cancer was located in the head of the pancreas, in the second in the tail, in the third both in the body and the tail, and in the fourth the entire organ was invaded.

The most frequent location of metastases was the liver, to be followed in descending order of frequency by the lungs, lymph glands and peritoneum. The largest tumor was the size of a newborn child's head.

Metastatic tumors were found nearly exclusively in the male sex, mostly in the sixth decade of life, with the location of the primary tumors in the gall bladder, biliary ducts, esophagus, and lungs.

JOSEPH K. NARAT, M.D.

Ceballos, A., Brachetto, Brian D., and Rosenblatt, B. Insular Adenoma of the Pancreas. The First Case in Argentina. (Adenoma insular de pancreas. Primer caso Argentino) *Arch. Soc. argent. med.* 9:44, 6 309

A woman, age 37, had been complaining for 4 years of attacks of nervousness, profuse perspiration, and tremor during the preprandial periods which disappeared after the ingestion of food. Hypoglycemia, accompanied by general debility, tremor, perspiration, mental confusion, found at the clinical examination could be relieved by the ingestion of carbohydrates or an intravenous injection of glucose solution. The differential diagnosis involved a spontaneous hypoglycemia or paroxysmal manifestation of some other condition. No signs of an involvement of the liver, hypophysis, thyroid gland, suprarenal glands, or the central nervous system could be found. Therefore, an adenoma of the Langerhans islets was suspected.

An exploratory laparotomy revealed an adenomatous nodule situated at the junction of the head and the body of the pancreas. The tumor had an ovoid shape 13 by 6 mm. in diameter. It weighed 155 gm. and was encapsulated. The parenchyma of the tumor had a whitish color and an adenomatous aspect. The tumor was divided by fibrous bands into alveoli. The microscopic examination disclosed two types of cells: () high cylindrical cells with a clear cytoplasm and irregular ovoid nuclei, and ()

low cuboid or pyramidal cells with a chromophilic protoplasm and pyknotic nuclei. The latter type of cells was in the minority. JOSEPH K. NARAT, M.D.

Bianchi, A. E.: Pancreatic Insular Carcinoma (Neuroblastoma) with Generalized Metastases (Carcinoma insular pancreatis [neuroblastoma] con metastasis generalizadas) *Arch. Soc. argent. med.* 9:44, 6 497

Since the publication of the first case of insular adenocarcinoma in 1927 numerous articles have described benign as well as malignant tumors originating in Langerhans islets. In 1938 Laidlaw suggested the term "neuroblastoma" for tumors originating in the islets and the term "neuroblastoma" for hyperplastic reactive changes of a non-neoplastic nature.

The author of this article collected from the literature 120 cases of benign tumor involving the pancreatic islets.

He observed such a tumor in a woman, age 39, who was admitted to the hospital with complaints of intensive premenstrual pains in the left axillary region, occasionally radiating to the right shoulder. The complaints were of one year's duration. The patient also had pains in the lumbar region radiating into the lower extremities. At the time of admission numerous white or bluish nodules were found scattered throughout the body. A bloody expectoration of 3 days' duration was present.

Among the important findings the following may be mentioned: the blood sugar was 117, albumin, sugar, and acetone were found in the urine, the Kahn reaction was negative and the blood count and differential count were normal. Examination of the contents aspirated from one of the nodules revealed nondifferentiated neoplastic cells. Aspiration of the liver was done and the microscopic examination showed large cells with round nuclei and polygonal protoplasm. These cells resembled those found in the cutaneous nodules. The identification of the neoplastic cells was very difficult. Atypical mitoses were noticed. A blood examination 2 weeks after admission showed the presence of myelocytes, metamyelocytes, and normoblasts.

The febrile condition led to a fatal outcome. The autopsy revealed cystohemorrhagic formations in the liver, nephrosis, hemorrhagic ovarian cysts, hemoperitoneum and hydrothorax on the right side. A circumscribed mass was found in the pancreas which showed a diffuse enlargement.

The histological examination disclosed a generalized endothelioma, partially solid and partially with the characteristics of a hemorrhagic angioendotheliomatosis. Various staining methods, such as Mallory's and Van Gieson's, and thionine, allowed a diagnosis of a neuroblastoma originating in the Langerhans islets. The author calls attention to the fact that the blood sugar level remained normal and that numerous metastases spread through the blood as well as the lymph system.

JOSEPH K. NARAT, M.D.

MISCELLANEOUS

Etherington-Wilson W. Torsion of the Great Omentum. *Brit J Surg* 1945 33 143

A review of the literature on torsion of the great omentum yields some 190 cases of all varieties, of which 75 can be considered of the primary or idiopathic type. The author reports 4 cases, of which 1 was primary 2 were bipolar with a pelvic adhesion, and 1 was swollen and infected by tubercle bacilli. The 4 pathological specimens are illustrated.

The great omentum may twist as a whole or as a part or strand either may be complete (strangulated) or incomplete (congested) either may be primary or secondary. Primary twists are necessarily intra-abdominal and unipolar and no definite cause can be ascertained. In cases of secondary rotation, the condition may be unipolar or bipolar, and occur as a result of hernia adhesion, omental deformity or past or present intraperitoneal inflammation. The condition may be acute subacute or recurrent. A combination of factors is probably responsible for the causation of omental torsion, such as Peristaltic pushes by the muscle of the intestines abdominal wall, and diaphragm sudden jerky body actions and rotations direct blows omental disfigurement by tumors overloading or uneven fat distribution pedicle formation scarring ruggedness adhesions and bipolar attachments displacement of the omentum during operation or by abdominal tumors. A history of all such causes is found among the cases recorded. A partial twist having started and caused congestion of the veins with edema, it has been suggested that the shorter and firmer arteries may complete the omental twisting. Males are more often affected than females, which may be accounted for by trauma or exertion. The condition is uncommon at the extremes of age.

The condition is rarely diagnosed or even suspected. Over 80 per cent of cases are diagnosed as appendicitis, and a much smaller number as perforated ulcers or cholecystitis. The following points are worthy of notice and should lead to the correct diagnosis on occasion. The patient probably from 20 to 55 years of age, and a male gives a history of right-sided abdominal pain which gradually gets worse, is often in spasms and is usually relieved by lying down. Other symptoms and signs are not pronounced and are of little differential value. Tenderness and rigidity are not impressive. There may be a history of undue exertion or accident, and a hernial scar or sac may be present. The palpation of a doughy tumor in the midline or to the right, often above the appendix is a suggestive sign.

The treatment consists of early exploration. The omentum, or a part, is almost always removed. Occasionally as in one of the cases reported here the strangulated omentum is simply untwisted. Apart from complications which are remote, few patients have succumbed to the abdominal condition.

JOHN L. LINCOLN M.D.

Eaton, R. B.: Forward Abdominal Surgery. *Canad M Ass J* 1946 54 19.

The author relates his personal experiences and observations, and the lessons learned during the surgical treatment of 230 patients in a Forward Surgical Unit at an advanced Surgical Center with the R.C.A.M.C. The experience began in Normandy and ended in Northwest Germany and Holland. Twenty-one of the patients had acute abdominal lesions all others presented battle casualties of first or second priority. There were 38 deaths.

The time interval from injury to operation the distance and the extent and site of the injuries are stressed as the most important factors in the outcome of the cases. In abdominal cases the optimum time was from 6 to 8 hours and the distance from 10 to 15 miles. The optimum time for operation after resuscitation had begun was left to the judgment of the resuscitation officers who became exceedingly skilled in their ability to determine the correct moment for surgical intervention. Pulse volume and the restoration of peripheral circulation were considered the best guides to the optimum time for surgery. Blood pressure was considered of less importance as it was often difficult to get the blood pressure above 80 to 90 mm Hg thus a stable blood pressure plateau was of more importance than the height of a single reading. If the optimum time for surgery was missed secondary resuscitation was usually impossible and a state of irreversible shock was likely. However, no abdominal case was considered hopeless until a laparotomy had been performed even though the response to resuscitation was not good.

The diagnosis was usually obvious and clear cut. It consisted mainly of determining the general condition of the patient, and the number and course of his wounds. Audible peristalsis usually ruled out an intraperitoneal lesion, but flank wounds with lacerated colons were exceptions. Chest wounds produced transient abdominal signs which were confusing but which disappeared with rest and resuscitation. Exploratory laparotomy was resorted to when there was doubt as to the existence of intra-abdominal wounds.

Routine exploratory laparotomy incisions were used in most cases but occasionally transverse incisions from the outer border of the erector spinae to the rectus muscle were used. They gave excellent exposure for flank wounds with kidney involvement, and made it possible to deal with the kidney first and then open the peritoneum to explore the peritoneal cavity. Abdominal laparotomy wounds were occasionally carried through the costal margin, which was reflected to give good exposure of the diaphragm liver and cardia.

The rule for the management of large bowel wounds was mobilization and exteriorization. Multiple wounds of the cecum and ascending colon required exteriorization, while less extensive ones could be sutured, and in both cases a short-circuiting Rhotransverse colostomy was done. Occasionally

wounds of the cecum and ascending colon were simply sutured and a drain inserted to the area. Spurs were feasible with left colon colostomies but gave difficulty and if used should not be over 2 inches long. Multiple wounds of the colon, and pelvicolon wounds were sutured distal to a safety colostomy. Drainage was done in all cases of large bowel contamination.

Small bowel wounds were preferably sutured. Resection was necessary for multiple wounds and for wounds involving the mesentery. A single long resection was preferred to multiple short ones. End-to-end anastomosis was preferred, with a double-layer running suture and a few interrupted reinforcing sutures.

Wounds of the spleen were always treated by splenectomy. Wounds of the stomach were closed primarily with care to watch for posterior wounds when an anterior one was found. Wounds of the pancreas carried a high mortality and were treated by suture and drainage.

Lacerations of the liver were handled by deep sutures and occasionally were reinforced by omentum, but packs were avoided. Drainage to the site of injury was considered essential.

Bladders were closed in two layers with a cystostomy, care being taken to place the suprapubic tube high in the fundus of the bladder.

Spilled intestinal contents and blood in the peritoneal cavity were carefully sucked out at the beginning of the operation. Abdominal wounds were closed in layers: interrupted chromic catgut (No. 2 or 3) sutures were used except in the peritoneum. Sulfadiazine was used in the peritoneal cavity but its value was questionable. Sulfathiazole-penicillin powder was dusted into the wounds before closure of the skin.

The patients were kept from 10 to 12 days, and postoperative care was meticulous with adequate blood, plasma, and fluids. Penicillin (100,000 units per 24 hours) was used routinely and sulfa drugs were used when indicated.

Complications were few. Evisceration occurred in only 2 cases. Peritonitis, as it is known in civilian practice, was rare and only 1 patient was thought to have died of general peritonitis (not proven by post-mortem examination). There was not a single instance of fecal fistula in this series of cases. Other complications were those usually found in extensive abdominal surgery. FREDERICK C. HOSKIN, M.D.

GYNECOLOGY

UTERUS

Masclottura, E. and Baldi E. M.: Acute Torsion of the Fibroid Uterus (Volvulo de utero fibromatoso o torsion aguda de ntero fibromatoso) *Rev med chir pat fem* B Air 1945 23 512.

Two cases of acute torsion of a fibroid uterus seen during 6 years on an active gynecological service are reported. The patients presented themselves with signs and symptoms of an acute gynecological abdomen, having had trouble for 6 months and 2 or more years, respectively. There were severe intermittent abdominal pain fever and tachycardia but no signs of direct peritoneal involvement. A lower abdominal mass was palpable which produced pain on motion. Pelvic examination confirmed the presence of a nodular mass in the pelvis which prevented definite palpation of the uterus. A diagnostic sign of importance is considered to be the detection of the pulse in the uterine artery anteriorly.

Both cases were considered to be torsions of the uterine body on the cervix around the long axis of the organ. These torsions were partial as the cervix was spared in the process and incomplete because the rotation was less than 360 degrees. (The authors suggest volvulus as the diagnostic term when the cervix is not included and axial rotation when both body and cervix are implicated.) This displacement explains the anteriorly palpable pulse of the uterine artery.

Both patients were subjected to subtotal hysterectomy and made uneventful recovery.

HIRAM T. LAWORSTON M.D.

ADNEAL AND PERIUTERINE CONDITIONS

Gullner A. The Relation of the Theca Cells to Disturbances of the Menstrual Cycle *J Obst Gyn Brit Empire* 1945 52 545

The author introduces this article with a review of a previous study on the relationship between theca cells surrounding the ovarian follicles and disturbances in the menstrual cycle of the baboon. He believes that in the human being many menstrual upsets have been attributed to the presence of atretic or cystic follicles, while consideration of the accompanying masses of theca cells has been neglected.

The material from which his conclusions have been drawn for this discussion was collected from ovaries and uteri obtained at operation upon women who had complained of excessive uterine bleeding or other symptoms of endocrine disorder. There is no tabulation of the cases but a running discussion is given in which the development and changes in the theca cells are described for the primordial follicle corpus luteum atretic follicle luteal cyst, and the corpora albicantia.

The author describes luteinization of the theca cells around atretic follicles in ovaries with a co-existing corpus luteum, and differentiates between the luteinized theca and granulosa cells by the presence of blood vessels in and about the cells of the theca. Such vessels were not found to permeate the granulosa cells, although in corpora lutea the vessels extended between the lobules of the cells, but not among the cells themselves. He noted an intense vascular response with capillary hemorrhage into the interstices of the theca cells as a frequently associated finding in diffuse theca luteinization.

Theca cell luteinization around atretic follicles may be without clinical significance in ovulatory cycles. The formation of extensive areas of lutein theca cells may be visible macroscopically around the follicles but in other instances the association with the follicle may not be readily apparent. The most frequent type of change noted was one in which the cells were found to be similar to those seen as the paraluteal cells of an approximately 30 day old corpus luteum. Similarity to the cells of the adrenal cortex was emphasized.

The author states that the character of the uterine reactions associated with theca cells is such that neither estrogenic nor progestational influences can be attributed to them. Their activity suggests to him a third ovarian hormone which may exert androgenic activity or a modified secretion of the known varieties which is capable of distorting the balance between simultaneously acting steroid hormones of the menstrual cycle. GEORGE BRADBURN M.D.

EXTERNAL OENITIALIA

Novak, E. and Stevenson, R. R.: Sweet Gland Tumors of the Vulva, Benign (Hidradenoma) and Malignant (Adenocarcinoma) *Am J Obst.*, 1945 50 642

The most common location of sweat gland tumor of the vulva is on the labia majora and the next most common is in the perineal skin or perineum. The gross appearance of the lesion varies. It is always small rarely reaching a size larger than that of a cherry and usually not over 1 cm. in diameter. It may present as a small firm subcutaneous nodule like a small skin fibroma, covered by intact skin. In other cases it is soft, resembling a small sebaceous cyst, for which it is commonly mistaken. Not infrequently there is a small superficial granular area on the surface. If pressure is made on the small nodule, one is apt to be surprised by the fact that, instead of a typical sebaceous exudate the material expressed is reddish brown and pulpy. This should at once suggest the real nature of the lesion. There is no pain and often no tenderness or soreness especially when the skin surface is intact, and the nodule is ordinarily quite movable. In a consider

able number of cases the patient herself has not noticed the nodule, its removal being incidental to vaginal operative procedures.

The sweat gland tumors of the vulva constitute a relatively rare but highly interesting group. Clinically they present as small and innocent looking growths on or near the vulva, but to one not familiar with their histological appearance the microscopic picture is apt to be rather startling and perhaps lead to the diagnosis of adenocarcinoma. However in only 1 case in the literature that of Elchenberg was there apparently unquestionable evidence of malignant change, both clinical and microscopic. All other cases, including the 15 cases reported herewith, were clinically benign and all have been cured by simple excision.

Granted that the characteristic microscopic picture of these growths might well in other tissues lead to the diagnosis of adenocarcinoma, there would seem to be no justification for applying the term adenocarcinoma to these notoriously benign sweat gland tumors. It is entirely possible, and perhaps even probable that some instances of the rare primary adenocarcinoma of the vulva may be of sweat gland origin, as in 2 cases of the group included in this article. Such an origin however is difficult to establish.

Fifteen cases in white women are reported, the youngest being 28 years and the oldest 67

EDWARD L. CORNELL, M.D.

MISCELLANEOUS

Aguilera de Alvarez, M. D.: Action of the Synthetic Estrogens on the Metabolism of the Lipids (Acción d los estrogenos sintéticos sobre el metabolismo d los lípidos) *Arch. farm. biolém., Tucumán*, 1945: 33

This study concerns the relationship between the estrogenic hormones and the metabolism of the lipids in the mammal, and compares the results of the author with those obtained by other authors in the viviparous vertebrates. The synthetic hormones were used exclusively since they are the easiest to obtain and their results are, in general, similar to those of the natural hormones. By the lipids the author means that heterogeneous group of substances characterized by their insolubility in water and solubility in the so-called fat solvents such as ether, chloroform, boiling alcohol, petroleum and ether. The tissues of the experimental animals used (castrated and normal rats) were extracted with alcohol and ether according to a slightly modified method of Bloor. Total phospholipids were extracted and determined according to Folke and Subbarow with the photometer of Pulfrich. The choline fraction of the phospholipids was then determined by the technique of Marend and Cardini (*J. Biol. Chem.* 1943, pp 363-371) also the values for sphingomyelin. Finally the values for cephalin were calculated by subtracting those of the choline phospholipids from the total phospholipids, and the lecithin was

calculated by subtracting the values for sphingomyelin from the choline phospholipids. The author's determinations are given in extensive tables in the original article, and in every instance compared as a norm with the figures given by the aforesaid work of Marend and Cardini.

In all the organs of the noncastrated animals injected with stilbestrol propionate there was a relatively marked decrease in total phospholipids, with no change in the plasma values. The lecithin showed an increase in the brain and kidney and a decrease in the heart and lung without appreciable change in the spleen and liver; the cephalin exhibited an appreciable increase in the heart and blood plasma, but otherwise had decreased more than 90 per cent. In the normal animals injected with propionate of stilbestrol the sphingomyelin displayed an enormous decrease to mere vestiges in some organs or even to complete disappearance.

In the castrated animals the movement of the values in every instance tended to follow those exhibited by the normal animals except that the changes tended not to be so pronounced.

When the values for the cited lipid fractions are compared with the values for total phospholipids instead of with the normal values established for noninjected animals by Marend and Cardini, it is seen that in normal, that is, noncastrated, animals with injections of stilbestrol, the lecithin shows a tendency to increase, while in the castrated animals, it has a tendency to decrease, the cephalin following the inverse course. Although the sphingomyelin decreases in the castrated animals, it does so in a lesser degree than in the normal animals. Castration seems to inhibit in part the effects of the stilbestrol on the phospholipids of the tissues.

JOHN W. BRIDGMAN, M.D.

Schaob I. C. and Davis, J. E.: The Significance of Streptococci Isolated from the Female Urinary Tract. *Bull. Johns H. Philip Hosp.* 1945: 77-772

A review of previous reports in the literature clearly shows that with the exception of alpha and gamma enterococci (often grouped as streptococcus fecalis) the relation of streptococci to infection of the urinary tract has received little attention. The present authors have determined the incidence of streptococci in a series of 9,053 consecutive cultures from catheterized urine specimens of obstetric and gynecologic patients.

The organisms were isolated and identified by accepted procedures, and classified as follows: alpha streptococci, beta streptococci, gamma streptococci, alpha and beta enterococci (streptococcus fecalis) and microaerophilic streptococci. The beta streptococci were further classified into serological groups A, B, C, and D, and "streptococcus" group not determined. This last group included organisms that had failed to react with antisera of the other four groups. It is the group A beta streptococci which are highly pathogenic for man, the cause of the acute and severe streptococcus infec-

tions, and the most frequently isolated from clinical material

In the authors series streptococci occurred in 159 cultures, an incidence of 11.8 per cent of the total number of cultures. Of the total number of streptococci 54 per cent were alpha and gamma enterococci 49 per cent were alpha streptococci 12 per cent were beta streptococci and the small remainder were divided among the other categories. Organisms of the highly pathogenic group A beta streptococci were found in only 3 cases in the entire series. The relative incidence of these organisms judging by their incidence in other clinical material is the reverse of what might be expected. Therefore, the case histories of 500 gynecologic patients from whom these organisms had been isolated were studied in order to determine the pathogenicity of the various streptococci in the female urinary tract.

Streptococci were found to be the sole cause of clinical disease in 35.2 per cent of the cases reviewed and were found to be involved with other organisms in 38.8 per cent. They were regarded as etiologically significant in 54 per cent of the cases.

The relative occurrence of the various streptococci with *Escherichia coli* was studied and it was determined that the alpha and gamma enterococci were involved with *Escherichia coli* in a significantly higher percentage of cases than the other streptococci with the exception of the gamma streptococci.

In 40 per cent of the patients from whose urine streptococci were isolated, no clinical evidence of urinary tract disease could be found in the history. The authors suggest the possibility in these cases that the streptococci may have been the cause of a past disease or may be responsible for future exacerbations of urinary symptoms.

L. JAMES TALBOT M.D.

Stoltz, H.: Malignant Tumors of the Female Genital System (Tumores malignos do aparelho genital feminino). *An. brasil gin., 1945* 20 327

A review of the cases of malignancy of the female generative tract seen over the 10 year period from

1935 to 1945 and an account of the improvement of the facilities for conducting such work at the Clínica Ginecológica da Faculdade Nacional de Medicina of the University of Brasil in Rio de Janeiro are presented. The results are in accord with the general figures with regard to the location of the neoplasm, age and race incidence as well as the histopathological types and relation to the births.

On the basis of severity these cases are classified into four groups according to the League of Nations standards. Of the cases of cancer of the cervix (224 cases) 7.3 per cent were early cases and only 33.9 per cent were in groups I and II combined.

The most frequent organ involved was the uterus. Among the 277 cases (29 recurrent lesions) including lesions of the bladder, sigmoid colon, rectum, mesentery, breast, and uterus lesions of the uterus accounted for 134 of them, 220 being in the cervix, 4 in the cervical canal and 10 in the body.

The treatment given is determined by the degree of invasion, the histological type, and the presence and extent of secondary infection. Surgery, radium and roentgen therapy are used in various combinations. Some details of the irradiation technique are given.

Much improvement in diagnostic and therapeutic methods has occurred. For the first five year period the results may be given as follows: of 114 patients treated, 16 died during treatment and 31 were given only palliative therapy. Of the remaining 67, 10 or 14.9 per cent presented clinical cures after a period of 5 years.

The local socioeconomic factors influencing admission for early diagnosis as well as the end results are discussed. Numerous detailed tables are presented showing the frequency of location of the lesions by organs, percentage distribution by degree of invasiveness in cervical lesions, frequency of the histopathological types in all organs, the age, color and parity factors, concomitant disease, incidence of the family history of neoplasia, previous surgical operations and the frequency of various therapeutic methods which were applied.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Leverson, R. M., and McMillan, T. J.: Meat for Pregnant Women. *J. Am. M. Ass.* 1946 30:234.

The importance of adequate protein intake to mother and child has been well established. The investigators endeavored to see the results from the simple dietary recommendation "Eat plenty of meat—have a generous serving at least twice a day."

Private patients, all under 33 years of age, were selected. In addition to 3 regular meals per day they received 5 ounces of lean meat. Two control groups were used. All the women were about in the same stage of pregnancy and had the same hemoglobin. One group was given vitamin B complex supplement, while the other group received no supplement. These additions to the diet of meat and Vitamin B were begun early in the fifth month of pregnancy and continued for three months after delivery.

The women whose intake of protein was augmented by receiving a 5 ounce serving of meat daily had higher hemoglobin and red cell values, less edema, and more success in lactation than the women who received a supplement of B complex or those who received no supplement.

CATHERINE B. HESS, M.D.

Ware, H. H., Jr., and Winn, W. C.: Ectopic Pregnancy. *South. M. J.* 1945, 39 44.

The early diagnosis of ectopic gestation is dependent on the following:

- 1 Abdominal pain usually unilateral, frequently described as sharp lancinating stabbing or tearing, but sometimes cramplike and usually intermittent even though dull. The pain usually has a definite onset and is frequently noticed after exertion or defecation, and sometimes after intercourse. The severity of shock is in proportion to the rapidity of onset and the amount of internal hemorrhage.

- 2 A careful history which reveals an irregularity of the menses, either in interval or amount and in duration of the flow. Amenorrhea for one month or more is frequent in ectopic gestation.

- 3 The presence of a unilateral tender boggy pelvic mass, which was diagnosed in 60 patients, or 51 per cent.

- 4 Manipulation or pressure on the cervix. This causes severe pain in most cases.

- 5 Slight bloody vaginal discharge, which was observed in 75 per cent of the patients.

- 6 A rapid pulse rate associated with low hemoglobin, and a normal or slightly elevated temperature. This is very suggestive of ruptured ectopic gestation.

- 7 Pelvic examination. This should be extremely gentle and limited to one if possible.

Titus says "Expectant treatment for an ectopic pregnancy at any stage and in any location is highly

hazardous, as the sac may rupture without a moment's warning and the patient die from the ensuing hemorrhage." The authors emphasize that operation for removal of an ectopic pregnancy should be done as rapidly as possible after the diagnosis is made.

CHARLES BAROW, M.D.

Barnes, J., and Browne, F. J.: Blood Pressure of Relatives of Patients with Toxemia of Late Pregnancy (Preliminary Note). *J. Obst. Gyn. Brit. Empire*, 1945, 52 559.

The authors present a preliminary report on a study which is in progress to determine what part, if any, a familial tendency toward hypertension plays in the etiology of the toxemias of pregnancy. Estimations were made on 226 blood relatives of 130 patients who had been admitted to the obstetric unit of the University College Hospital in London because of toxemia. Estimations on a control group of 66 relatives of 47 patients who were normal were also made.

There was no demonstrable difference in the blood pressure recordings between the relatives of toxemic and those of the control patients except in the group of toxemic women with essential hypertension associated with pregnancy. In this group it was perhaps significant that 16 of 18 mothers showed definite hypertension.

GEORGE BRADSHAW, M.D.

Calvo, J. A.: Brow Presentation. Four Cases Observed in the Maternity Clinic in Bogota (A propósito de la presentación cefálica en posición de frente y de cuatro casos observados en la Clínica de Maternidad de Bogotá). *Rev. Obst. Gyn. Caracas*, 1945, 5 46.

In 4 instances of labor in brow presentation, all in young primiparas from 20 to 26 years of age, the pregnancy had been completely normal with delivery at term of normal babies of about normal weight from 3 060 to 3 740 gm. In all, the pelvis and birth canal was without abnormality yet the duration of labor was markedly beyond the normal for this type of presentation and no infant was delivered spontaneously. One child however was the only mortality.

In the first patient premature rupture of the membranes rendered manual dilatation of the cervix necessary. Attempts at conversion of the presentation into the face or vertex variety, and attempts at high forceps failed, and a dead child was delivered after 70 hours of labor by a high, laborious baco-tripsey. After this amount of manipulation the patient's puerperium was naturally stormy with fever, a painful uterus, fetid lochia, and endometritis.

In the second case the membranes were ruptured after nearly 4 days of labor and the cervix was dilated to a diameter of 3 cm. However after a further 7 hours of strong pains the head was still mobile

and dilatation had not greatly advanced a cesarean section was done with happy results for both the mother and child.

Opposition of the relatives to a cesarean operation and the slow but relatively favorable progress in the third delivery of this series induced an expectant attitude, at least until dilatation should be complete. This decision was made at consultation 33 hours after the initiation of labor at which the consultants insisted that delivery would occur spontaneously in a few hours. Yet 13 hours later after 5 hours of powerful labor pains and although dilatation was complete and the head had rotated from the mento-posterior to the mentoanterior position the membranes had not yet ruptured, and the consultants now acknowledged the necessity of interference. A difficult forceps operation resulted in the delivery of a living child.

In the fourth mother of this group the fetal head became fixed in the pelvis 16 hours after the initiation of labor and an hour later the membranes ruptured prematurely with rapid dilatation of the cervix. Eight hours later in the presence of continuous violent labor efforts the head became fixed in the right mentoposterior position a finger breadth from the perineum. A relatively easy forceps operation resulted in the extraction of a living child in the mentoposterior position.

His own experiences and a perusal of the medical literature brought the author to certain conclusions which he hopes may prove of value to the practicing physician.

These conclusions are rather briefly as follows:

1. Brow presentation causes grave dystocia even with a normal pelvis and small fetus.
2. Spontaneous delivery in this condition is rarely seen.
3. In the presence of concomitant complications cesarean section is frequently an adequate procedure and the least difficult one.
4. Recourse to sedatives and antispasmodics is of great value while waiting for spontaneous delivery and while preparing for intervention.
5. The technique of procedure should be chosen according to the individual case to safeguard the life of the mother and child the operator being guided, of course by the following considerations: (a) a reasonable period of waiting; (b) resort to cesarean section when vaginal delivery can be anticipated to cause difficulty and there is still time for surgery; (c) the use of forceps when the head is fixed in the pelvis with deep anesthesia and previous episiotomy; (d) symphyotomy if indicated and finally (e) basiotomy when the expectant period has proved a failure, or when negligence or lack of comprehension of the physician renders this disagreeable procedure obligatory.
6. Patients with brow presentation should be transferred to a specialized clinic or hospital to be cared for by a competent personnel and where everything will be ready to cope with any complication which may arise.

7. The obstetrician should be above everything a good doctor and combine common sense with his technical knowledge. JOHN W. BREXHAM M.D.

Thomas, R. C.: Rupture of the Rectus Abdominis Muscle during Pregnancy. *J. Obst. Gyn. Brit. Em.* 1945 52: 580.

The author reports on his second case of ruptured rectus abdominis muscle during pregnancy. The number of such cases reported in the literature is 31. Eighteen of the 31 cases gave a history of respiratory trouble 5 occurred with the onset of labor 2 followed a fall and 1 case occurred after labor during the course of typhoid fever. Of the 31 patients, 3 were primigravidae, 24 multigravidae, and in 4 the parity was unknown. The treatment in 20 cases was operation 4 of the patients died.

The difficulty in diagnosis is great, shown by the fact that in only 9 of 32 cases the correct diagnosis had been made.

The symptoms in the author's case that of a 34 year old para vi who was 33 weeks pregnant, were faintness pain in the right side and vaginal bleeding with a history of bronchitis for 2 weeks. Examination revealed Cullen's sign and an extremely tender uterus most of the tenderness being above the uterus. The hemoglobin was 49 per cent. Surgery was advised and 30 ounces of fresh and old blood were removed from the whole length of the posterior aspect of the rectus muscle extending up to the right costal margin and down to the symphysis pubis. All of the bleeding vessels were tied and the cavity was packed. Five days after the operation the patient went into labor and delivered a 3 pound 12 ounce stillborn female. CATHERINE B. HALL, M.D.

Shute, W., and Browne, F. J.: The Prevention of Premature Labor. *J. Obst. Gyn. Brit. Emphre* 1945 52: 570.

A series of 63 cases of threatened premature labor with a resultant salvage of 73 per cent is presented. This problem is acute according to some statistics. In 1941 there were 144,693 fetal and neonatal deaths in the United States. The estimated number of premature births in the United States in 1942 was 155,000 and 33,500 of the premature infants died in the first month of life. The solution of the problem does not seem to be in saving premature infants but rather in preventing premature births.

In this study it was found that a tendency toward premature labor could usually be predicted by finding a blood estrogen excess in early pregnancy. This occurred in 87 per cent of the 38 cases tested. A blood estrogen test is made routinely at the patient's first prenatal visit. This serves as a guide to the danger ahead.

Patients developing uterine tenderness, sacral backache spotting loss of amniotic fluid or a feeling of prolapse or impending menstruation are treated with Vitamin E. Only large daily doses of from 75 to 125 mgm of alphatocopherol are effective. These and larger doses can be given throughout pregnancy.

until term. This was the only therapy given with or without temporary rest in bed.

Among the 109 patients included in this and a previous report, there were 6 monsters and 93 normal living children delivered.

CATHERINE B. HESS, M.D.

LABOR AND ITS COMPLICATIONS

De Gouca, L. R. L.: Delivery of the Transverse Presentation (*O parto em apresentação cômica*) *Arch. brasil med.* 945 35 39.

This article comprises a rather complete discussion of delivery of the transverse presentation, and includes 38 references.

A brief historical review indicates that the condition was recognized even by the more primitive races and that they undertook some measures for its correction.

Consideration of the etiology, incidence, varieties, diagnostic maneuvers, clinical course, prognosis, and prophylaxis are presented in considerable detail as are the methods of treatment.

The author's own cases, 10 in number, were seen over a 4 year period. The incidence based on a 37 month period from June 1, 1941 to July 1, 1944, revealed transverse presentations in 0.64 per cent of 3,735 single pregnancies and in 5.3 per cent, for the second fetus, of 75 twin pregnancies. Of the 10 cases managed 8 were single pregnancies, 1 was of twin pregnancy (second child) and 1 was an abortion. The cause for this presentation in 9 of these cases was believed to be due to failure or inability of the uterus to maintain proper control over the fetus either because of laxity or flaccidity of the former or small size of the latter and in 1 case it was due to multiple pregnancy.

Two cases of spontaneous delivery occurred once by conduction corpore with a macerated 8 month premature infant and again by the mechanism of Douglas in an abortion occurring in the sixth or seventh month of pregnancy. Two cases were managed entirely satisfactorily by version and

extraction. Five cases in which the fetus was dead were managed by destructive operations—decapitation—without maternal injury. One case with ruptured uterus and peritonitis was seen the woman had been in labor more than 48 hours because of a prolapsed hand. Laparotomy was performed but the patient succumbed. HIRSH T. Gordon, C. A.: Hemorrhage as the Most Frequent Cause of Maternal Death. An Analysis of the Puerperal Deaths in Brooklyn, 1944. *Am. J. Surg.* 945 70 77.

Each year since 1938 the Brooklyn Committee on Maternal Welfare has analyzed in detail the maternal mortality. In 1944 there were 51,082 births and 62 deaths, a rate of 12.4 per 10,000. This represents a reduction of 8.1 per 10,000 over 1943.

Thirteen deaths occurred early in pregnancy: 10 from abortion and 3 from ectopic pregnancy. Toxicemia was responsible for 11 deaths. 6 infants were undelivered. Infection caused the largest number of deaths—30. Cesarean section was followed by 8 deaths (6 from infection and 2 from hemorrhage). Ruptured uterus accounted for 6 deaths (3 spontaneous, 2 following version and extraction, and 1 after forceps delivery).

Hemorrhage was considered as the primary cause of death in only 8 cases and as a secondary cause in 3 more cases. However, in reviewing the cases the author states that serious hemorrhage occurred in 33 cases. He does not believe, however, that it was the primary cause of death in all instances.

Although definite improvement in the maternal mortality was noted, further advances can be made. The record of deaths from hemorrhage is proof that the precautions against death from this cause are inadequate. Blood plasma is not sufficient in replacing the lost blood, the importance of adequate amounts of whole blood cannot be overemphasized nor can delay in replacement be condoned.

J. ROBERT WILLIAMS, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Larsen, K.: Method for Examination of the Function of Each Kidney Separately. *Acta med scand* 1945 123 56

The question of function of the individual kidney is highly important to the internist. The author found that insertion of ureteral catheters for measurement of individual kidney function was too inaccurate because urine ran alongside the catheters into the bladder. He presents a formula for calculation of the function of each side designating the amounts of urine produced by the right and left kidneys in the experimental period respectively as D and S , the amounts of urine collected through the right and left ureteral catheters respectively as d and s , and the bladder urine as Bl . He gives the following equation $D+S=d+s+Bl$.

If the urea concentration of the urine for the right and left ureteral catheters and from the bladder is respectively Ud , Us and Ubl the following equation is also true

$$DXUd+SXUs=d \times Ud+s \times Us+Bl \times Ubl$$

From these equations D and S and afterward the clearance from each kidney may be calculated easily. After introduction of the ureteral catheters the bladder is lavaged and emptied with a catheter after removal of the cystoscope. Then precisely 100 ml of water are introduced into the bladder and the collection of urine from the ureteral catheters commences. At the conclusion of the experimental period the portion of the bladder content which will run freely is evacuated. After this the collection of urine from the ureteral catheters is discontinued and immediately 50 ml. of water are injected into the bladder and withdrawn immediately after the first 10 to 15 ml. are discarded the following 10 to 15 ml are collected for analysis. If the urea concentration of this portion is designated as USk and the urea concentration of the bladder as Ubl that part of the bladder content that was not evacuated at once can be calculated from the equation

$$X \times Ubl = (X+50) \times USk$$

Therefore the amount of bladder urine is bladder content minus 100. In the second equation the last term is replaced by bladder content in ml $\times Ubl$. The results are controlled in the experiments by the determination of both the urea and creatinine clearance. This method is especially suitable for unilateral kidney lesions. Error may result in patients with pronounced hydronephrosis.

DAVID ROSENBLUM, M D

Rabotti F., and Magaldi, P.: Renobronchial Fistula (Fistula renobronchial). *Sem med B Afr* 1945 52 956

A woman, aged 39 years was admitted with complaints of persistent cough and pain in the left flank.

Nine years prior to admission she had had a stone removed from the left ureter and for 1 year she had had left serofibrinous pleurisy accompanied by renal colic.

One year prior to admission she had noticed a painful tumefaction in the region of the left kidney. A physician made an incision from which malodorous pus escaped. The remaining fistula has been treated with curettage local and oral administration of sulfanilamide, injections of prontosil and drainage. Injections of lipiodol into the fistula did not clarify the situation. Hemorrhagic purulent expectoration and subfebrile temperature did not yield to injections of calcium gluconate.

The local examination disclosed a fistula in the left costolumbar region from which a dense purulent secretion was escaping. The urine contained a considerable amount of pus. No tubercle bacilli were found in the sputum. The sedimentation rate of the erythrocytes was accelerated. X ray studies of the chest showed a diffuse shadow at the base of the left lung suggestive of a pachypleuritis. Poor elimination of uroselectan injected intravenously was noticed on the left side. Ascending pyelography showed sodium bromide solution in the left lung. Prontosil injected into the fistula appeared in the sputum. Indigocarmine injected intravenously appeared in the right ureter 5 minutes later while no dye was found in the urine from the left ureter for 15 minutes after the injection.

A left nephrectomy was performed and the patient made an uneventful recovery.

The authors conclude that a renobronchial fistula, although a rare complication should be kept in mind if a patient with symptoms of a previous renal or perirenal lesion complains of persistent cough with a purulent sputum. Nephrectomy usually cures the pulmonary process.

JOSEPH K. NARAT, M D

Fontaine, R., Forster E. and Ambard D.: Extirpation of the Aortorenal Ganglion in the Treatment of Painful Hydronephrosis (L'extirpation du ganglion aortico-rénal dans le traitement des petites hydronephroses douloureuses). *Rev chir* Par 1945 64 139

After unilateral nephrectomy the function of the remaining kidney is improved when the aortorenal ganglion is removed. The same favorable result is obtained in cases of painful hydronephrosis. The different surgical methods are discussed.

Resection of the splanchnic nerve and resection of the superior part of the lumbar sympathetic are mentioned as alternative methods to extirpation of the ganglion. In 7 of 9 cases the result was excellent. Partial improvement was obtained in 1 case and no success in 1.

Not only does extirpation of the ganglion give definite and lasting relief to the pain and colic, but it

improves the function of the kidney at the same time. It is still an open question whether the dilatation of the renal pelvis and ureter is also favorably influenced by the operation. The treatment is causal rather than symptomatic.

Cristol D. S., McDonald, J. R., and Emmett, J. L.: Renal Adenomas in Hypernephromatous Kidneys: A Study of Their Incidence, Nature, and Relationship. *J. Urol. Balt.*, 1946, 55, 18.

The resemblance between renal adenoma and carcinoma has been apparent to many pathologists.

The material used in this study was derived from surgically removed kidneys which were the sites of proved Grawitz tumors. A total of 567 kidneys and contained tumors were examined. The microscopic sections studied consisted of (1) 122 lesions suspected of being cortical adenomas, and (2) numerous sections of renal carcinomas located in the same kidneys from which proved renal cortical adenomas had been removed. The diagnosis could be verified in only 37 of the suspected renal cortical adenomas. All but one of these adenomas were largely papillary in structure. The exception was one that suggested an alveolar structure. As has been pointed out by many men writing on this subject, too often an adenoma will exhibit characteristics of more than one structural type. The largest adenoma in the series measured 4 mm. in diameter. The smallest was barely perceptible with a hand lens. More than 1 adenoma was found in 7 kidneys. The largest number of adenomas in any 1 kidney was 7. As with other investigators this series would indicate that there is an increasing prevalence of adenomas as well as of carcinomas in the decades past middle life.

Adenomas appear in the renal cortex as single or multiple grayish white yellow or brown nodules. They vary in size from that which is hardly discernible through a hand lens to the size of a walnut. Many are multiple and they are frequently found in both kidneys. Adenomas are seen to occur more frequently in kidneys containing clinical cancer than in significant series of kidneys examined at autopsy. Reasons are presented for considering adenomas as malignant growths.

Ackerman, L. V.: Mucinous Adenocarcinoma of the Pelvis of the Kidney. *J. Urol. Balt.*, 1946, 55, 36.

The case of a 66 year old man who presented a mucinous adenocarcinoma of the renal pelvis is reported. This is the first case recorded in the literature. The patient experienced attacks of renal colic at annual intervals 13 years. Eight years previously he was diagnosed as having a giant hydronephrosis and at that time a left nephrectomy was done. The kidney showed parenchymal destruction so that it was only a few millimeters thick in many zones. The pelvis and ureter showed alteration of the lining epithelium with evidence of chronic inflammation. Some areas showed squamous metaplasia and this

gradually underwent a transition to zones of piled up epithelium with vacuolated mucin containing cells which resembled morphology of the large bowel. In areas there were papillary projections similar to those seen in rectal polyps. The renal cortex showed hyalinized glomeruli and some cystic formation with flattened epithelial lining.

Six years following the nephrectomy a nonpainful swelling developed in the left flank along with abdominal enlargement which suggested intraperitoneal fluid and nodular masses. Under the left nephrectomy scar there was found an irregular mass firmly attached to the underlying structures. The urine showed much albumin with pus, bacteria, and occasional red cells. A needle biopsy of the mass showed a few cells forming acini, along with intracellular and extracellular mucin. The patient died within 6 months and the autopsy demonstrated a mucinous adenocarcinoma involving the liver, diaphragm, pleura, stomach, pancreas, and small bowel with lithiasis of the right kidney and squamous metaplasia of the pelvic epithelium. The significance of the spread is that it was not to the regional lymph nodes but resembled that of a pseudomucinous tumor of the ovary.

The author asks the interesting question as to why the left renal pelvis underwent glandular metaplasia and the right pelvis, squamous metaplasia.
ROBERT LACE, JR., M.D.

Fish G. W. and McLaughlin, W. L.: Liposarcoma of Kidney: Report of a Case Presenting an Unusual Syndrome. *J. Urol. Balt.*, 1946, 55, 28.

The authors report the case of a 28 year old white female with liposarcoma of the right kidney which is the eleventh such lesion reported and the seventh so reported in an individual with the tuberous sclerosis syndrome (knobby hardening of the brain). In addition, 3 additional cases in children are mentioned: (1) that of a boy of 7 years who showed tuberous sclerosis of the brain, and (2) that of a girl of 9 presenting the classical features of tuberous sclerosis, and although death ensued of cerebral lesions an autopsy was refused.

Tuberous sclerosis is discussed briefly in the article and attention is called to the concomitant findings of greasy gray red lesions of the face (adenoma sebaceum) in butterfly patterns and mental deficiency coupled with convulsive seizures. The presence of renal pathology is referred to and said to consist of either a single renal lesion although more often multiple bilateral neoplastic areas of primitive mesenchymal cell types (angio-fibro-endotheliomyo- and lipoblastomata) are found. The lesions are congenital deformities of the ectoderm and mesoderm, and demonstrate a strong hereditary factor. The individual with tuberous sclerosis seldom lives more than 30 years, and in every instance there is present the previously described skin lesion in 80 per cent of the cases the renal neoplasm is present. In a smaller percentage there is an associated rhabdomyoma of the heart, fibromatoma,

and malformation of other organs including the skeletal system.

The author's patient was seen repeatedly during a 4 year period. She had lesions of adenoma sebaceum and neurofibromatosis on her face back, and left fourth toe. There was a marked cardiac systolic murmur and a large abdominal tumor on the right side. There were no other significant findings except a profound anemia. Intravenous pyelograms showed an enlarged and distorted right renal pelvis. There was no familial history of tuberous sclerosis although one sister was confined for insanity and a brother was treated for intense phobias the patient herself was somewhat unstable emotionally.

The year before the patient was seen originally an exploratory celiotomy was done to ascertain the cause of fever abdominal tumor and anemia. A similar attack occurred a year later and the anemia on this occasion required the use of blood transfusions.

Three years later a similar attack of fever abdominal tumor, and anemia confined the patient to the hospital. On this occasion the tumor seemed larger. Another attack was experienced a year later and on this occasion the hydronephrosis showed progression along with elongation of the renal pelvis and calyces together with distortion suggesting hemorrhage. Upon nephrectomy the kidney substance was found to be almost completely replaced by various sized nodules of friable, grayish yellow tissue with nodules at the upper pole extending behind the liver. The total weight of the kidney tumor was 1,400 grams. The tissue showed cytologically encapsulated liposarcomas which were characteristically slow growing and nonmetastasizing but there was local recurrence and in addition, renal parenchymal compression.

The postoperative course was complicated by a severe transfusion reaction but at present (3 years following nephrectomy) the patient is working and claims to have unusually good health.

ROBERT LICH, JR., M.D.

Greene, L. F., and Kearns W. M. Circumcaval Ureter. Report of a Case with a Consideration of the Preoperative Diagnosis and Successful Plastic Repair. *J. Urol.* Balt. 1946, 55: 52.

The authors report a case of circumcaval ureter. This is the thirty third case reported the second preoperatively diagnosed and also the second successfully repaired surgically although it was the fifth in which such repair was attempted.

The patient was a 29 year old white male who had an attack of pain in the right costovertebral angle followed by the passage of urinary calculi a year prior to admission and then a recurrence of the pain 3 weeks before hospitalization. Excretory urography demonstrated a right hydronephrosis with dilatation of the upper third of the ureter which ended abruptly and at this point there was a gentle curve of the ureter with its convexity directed superiorly and medially the remainder of the ureter was normal.

Fig. Findings at operation. Surgical repair shown in inset.

The operative findings and repair are depicted in Figure 1.

The authors conclude that there is need of prolonged ureteral splinting after anastomosis of the ureter since in this case early removal of the splinting catheter was the cause of much concern, and the repeated introduction of ureteral catheters was necessary in order to reduce and finally obliterate the extravasation present at the site of anastomosis. The anastomotic site was splinted and drained for the greater part of 39 days postoperatively and the urinary infection was controlled by the use of one of the sulfonamides. Seven months after operation, at the time this article was written the urine was free of infection or any abnormality and the patient was asymptomatic. The kidney was almost normal, but ureteral dilatations at regular intervals were considered advisable.

ROBERT LICH, JR. M.D.

Soley P. J.: Ureteropelvic Obstructions in Children. *J. Urol.* Balt. 1946 55: 46.

Ureteral stricture was found once in 150 children when Campbell studied 10,000 routine antopsies. In 34 per cent of this group of children ureteropelvic obstructions were found and in 62 per cent ureteropelvic obstructions. In another series of cases studied by Campbell and Bottomly the same relative proportion of stricture location was found and too a similar distribution was found in adults. The significance of aberrant vessels in ureteropelvic obstruction is controversial but the association of these vessels is not disputed.

The symptoms of ureteropelvic obstruction in children are pain in the back and flank, gastritis

testinal disturbances and the associated vesical disturbances in the presence of pyuria including hematuria. The finding of a flank tumor is a late sign and in the case of a poor prognosis for the surgical restoration of the involved kidney. The laboratory tests for renal function were not found to portray accurately the end results following surgery. The author found that retrograde pyelography with delayed emptying more accurately demonstrated the lesion than the information obtained with intravenous urograms.

Treatment was discussed under two headings: (1) ureteral dilatations in early lesions and (2) surgery when dilatations failed. The purpose of surgery is to relieve obstruction and the coexisting infection. Ureteropelvic obstructions are considered to be either of intrinsic or extrinsic etiology; the latter most commonly due to an aberrant vessel. The fundamentals of surgical intervention are discussed and the use of ureteral splitting catheters is emphasized.

Nineteen cases are reviewed: 10 were in males and 9 in females; the ages of whom varied from 8 months to 4 years. The left and right sides were equally involved and in 5 instances bilateral obstruction was observed. Of these cases 6 were treated by dilatation by the Foley operation which was followed by improvement; 1 case was treated by severance of the aberrant vessel and nephrectomy with postoperative dilatation and good result was obtained by a bilateral nephrostomy and the use of splinting catheters with severance of a lithiasis; poor results were obtained both sides. Nephrectomy was done in 5 cases; the result: 3 failures, 2 heminephrectomy relieved the obstruction. In the lower duct in cases and left a important amount of functioning tissue in 2 cases and patient with bilateral involvement refused treatment of any kind.

ROBERT LEON J. M.D.

BLADDER, URETHRA AND PENIS

Weyde, R. The Treatment of Tumors of the Urinary Bladder. *Acta Med. Stockh.* 945: 26-58.

Weyde reports 55 cases of bladder tumor treated from 1932 to 1942 at the N. Wegner Rad. m. Hospital, Oslo, Norway. The average age of the male patients was 55 years and that of the women 60.4 years. Sixty-eight patients had leucosarcomatous bladder carcinoma, 60 had malignant papilloma or papillomatous carcinoma and 53 were in such poor condition that no palliative treatment was not given.

In the first 560 cases after the opening of the hospital primary roentgen therapy was usually employed although since at this time the patients would have received combined surgical and radiological treatment with higher roentgen doses. At this time the author administers protracted fractional irradiation of the field two frontal and two back. If possible a total dose of at least 5,500 r is administered to each field approximately 150 r

being given daily. A total tumor dose of approximately 5,500 r or more is given with 175 kv., 4 ma., 50 cm. F.S. distance and 1 mm. Cu filter. At present the author does cystoscopic electrocoagulation only of very small papillomatous tumors with narrow noninfiltrated pedicles and bases. Larger tumors are coagulated openly through a cystostomy.

In young people with one or several small papillomas, cystoscopic coagulation is done and followed by careful postoperative observation. On young patients with larger and more widespread papillomas cystostomy, coagulation and implantation of radium needles are performed. In middle aged and older people bladder papillomas are always treated as a carcinoma and the author's present method consists of cystostomy, electrocoagulation of the tumor, implantation of radium needles in the wound bed and postoperative roentgen therapy as soon as the incision is healed. The author uses 10 mgm. radium element needles in 1 mm. of platinum from 3/16" apart and attached to metal wires so that they may be removed in 24 hours. After the radium implantation a roentgen dose of from 7,500 to 4,500 r divided on four fields is given. Widespread tumors which are not removable through a cystostomy are given primary roentgen therapy and at times the tumor is so reduced in size that subsequent radical electrocoagulation and radium implantation can be performed. No cystectomies have been performed in this series.

The author believes that in both papilloma carcinoma and in infiltrating carcinoma, routine postoperative roentgen treatment is indicated, unless cystoscopic treatment will suffice. He has not attempted the use of the McCarthy resectoscope or of transurethral implantation of radium needles. Of the 155 patients, 111 are dead of carcinoma. Of 77 patients, 12 (14.3%) are living symptom free after 5 years and 30 (38.9%) are symptom free after three years.

D. M. ROBERTSON, B.S.D.

Lazarus, J. A. Primary Malignant Tumors of the Retrovesical Region, with Special Reference to Malignant Tumors of the Seminal Vesicles: Report of a Case of Retrovesical Sarcoma. *J. Urol. Balt.* 946: 35-90.

A case of primary sarcoma of the seminal vesicle is reported, with a critical review of the literature. The author states that only 3 cases of primary sarcoma of the seminal vesicle (including his own) and 20 cases of primary carcinoma of the seminal vesicle have appeared in the literature. Since carcinoma of the prostate shows a tendency to invade the seminal vesicles the author believes that only 7 of the 20 reported cases of primary carcinoma of the seminal vesicles can reasonably be listed as authentic. In the remaining 13 cases the prostate was involved in the malignant process and it is therefore not possible to state with certainty that the lesion originated within the seminal vesicle.

This disease is most prevalent among aged men and the left seminal vesicle is involved slightly more

frequently than the right. Urinary symptoms ranging from increased frequency to acute urinary retention were present in approximately 50 per cent of the cases in which the symptomatology was noted in the protocols.

Metastases in the regional lymph nodes, the liver and the lungs were reported in 12 of the 20 cases. The mortality in this group was approximately 85 per cent.

Because of the inability in most instances to differentiate clearly between intrinsic tumors of the seminal vesicles and the tumors designated by Young as tumors of the retrovesical space, the author believes that it is more correct to designate this group of tumors involving the seminal vesicles as primary tumors of the retrovesical space.

FREDERICK R. LIEBERTHAL, M.D.

Leadbetter W. F. Repair of Complete Tear of the Membranous Urethra. Case Report and Suggested Technique for Operation. *J. Urol. Balt.* 1945 54: 549.

During wartime tears or ruptures of the deep urethra may be caused by penetrating wounds or fracture of the pelvis with displacement or separation of the pubic ram. The latter is the usual mechanism producing this injury in civilian life. Because of the proximity to other structures such as penis, bladder and rectum, more than one organ is commonly injured. As a general rule, pelvic fractures are also associated with other injuries and the mortality is high.

The diagnosis of complete tear of the membranous urethra is simple if the possibility of it is borne in mind. There is usually slight meatus bleeding. Voiding is impossible if the tear is complete. Rectal examination reveals absence of the prostate from its normal position behind the symphysis. Because of bleeding or the accumulation of urine and blood in the space behind the symphysis, a soft mass is felt filling this region. A sound or catheter passed into the urethra will be palpated after its passage through the triangular ligament directly beneath the rectal wall. The passage of a catheter does not result in the withdrawal of urine, though occasionally some blood may appear. Once the diagnosis is made, operation as soon as possible is necessary for the bladder will empty into the perivesical tissues.

The operation of choice is one which approximates the prostate to the triangular ligament and repairs the urethral channel. The perineal operation is carried out as a primary procedure, accomplishing this. Generally because of associated injuries, only a suprapubic cystostomy is possible at this time and repair of the urethra is left for a later date.

The author presents a report of the findings and treatment in the case of a 23 year old soldier with complete division of the membranous urethra caused by a tank accident. There was a complete tear of the membranous urethra associated with simple fracture of the pubis as well as multiple skeletal injuries. A primary cystostomy was done.

Later it was found that the prostate had retracted after the injury, the apex having been pulled upward and pointed backward toward the rectum. The vesical neck was elevated and pushed forward. A cavity existed between the two ends of the cut urethra. Some urine was passed rectally. Urethral operation was subsequently performed. The urethra was threaded upon a catheter throughout its lumen and the prostate was pulled down to the triangular ligament by two heavy silk traction sutures through the prostatic substance on each side of the midline which were passed through the triangular ligament and the perineal tissues out on to the skin of the perineum toward the scrotum. The proximal urethra was similarly brought forward with silk sutures brought out to the skin.

The author proposes a new operation which would accomplish primary reposition of the prostate and satisfactory apposition of the torn ends of the urethra by the suprapubic route, possibly to be done primarily at the time of the first injury. After threading the entire urethra over a Foley catheter, the prostate is brought to the triangular ligament by silk traction sutures which are passed behind the symphysis directly through the perineal tissues laterally and through the perineal skin at the base of the scrotum. No attempt is made to repair the urethra proper. A guide of some kind should be kept in the urethra during healing until it is certain that instruments can be passed from below. This operation suggests instead of simple cystostomy.

DAVID ROSENBAUM, M.D.

Schourup, K. Plastic Induration of the Penis. *Id. ed. of Stockholm* 1945 26: 315.

The pathology of plastic induration of the penis is obscure. It consists of the formation of a thick plaque of fibrous tissue in the tunica albuginea of the dorsum penis and is probably caused by vascular changes. Cartilage or bone is deposited in the lesion in about 10 per cent of the cases. The incidence of this condition is low (26 cases among 30,000 genitourinary patients reported by Zustin and 12 cases observed among 22,000 patients at the Radium Center in Copenhagen). The only certain fact is the association of this disease in many cases with Dupuytren's contracture which is also rare. Generally 10 per cent of the cases have been reported as having both affections. Hamann found this association in 23 per cent of his cases and the author in 40 per cent of the cases presented in the article.

The diagnosis is rarely doubtful. Occasionally roentgenogram will help to show calcareous deposits in the wall of the penis. For the differential diagnosis: gumma, gonorrheal cavernitis, leukemia or tuberculous infiltrates and malignant tumors might be considered. They usually can be recognized by their location and the presence of ulcerations.

The medical and surgical treatment of this disease as well as a method of irradiation is discussed. The treatment of 11 cases is reported. Twelve were

Irradiated with x rays with from 300 to 3,000 r in fractionated doses moderate filtration long distance and short distance arrangements varying with the case, and the testicles shielded 3 cases underwent surgery and 2 were both irradiated and operated upon. The results were as follows

Group	Results	No. of cases
Fully satisfactory		3
Nearly satisfactory		3
Unsatisfactory		4
Not followed up		

Groups	and Results	No. of cases
Satisfactory		3
Less satisfactory		1
Unsatisfactory		

The principal beneficial effect was the alleviation of pain during erection which interfered with cohabitation.

The author concludes that radiation therapy should be attempted first the method of application being of minor importance and only if it fails should surgery be recommended

GERHART S. SCHWARTZ, M.D.

GENITAL ORGANS

Borthwick, W M: Tuberculosis of the Male Genital Tract. *Glasgow M J* 1945 44 73.

The author's discussion of tuberculosis of the male genital tract is centered mainly on epididymitis. The age incidence is essentially that of the period of greatest sexual activity. Of 43 males with tuberculous epididymitis 88.3 per cent had at least one extragenital tuberculous lesion. He does not find that antecedent trauma or nontuberculous infection plays any significant role in the etiology of the disease. Diagnostic signs listed in increasing order of pathognomonic value are induration, enlargement and nodularity of the epididymis thickening of the vas deferens, involvement of the prostate and seminal vesicles, chronicity and bilaterality of the findings and tuberculous bacilluria. In the differential diagnosis gonorrhea syphilis, neoplasm non-specific infection, epididymal cysts, trauma and torsion of the testis, and venous thrombosis of the pampiniform plexus must be excluded.

Tuberculous epididymitis was found to be bilateral in 56.47 per cent of the author's cases. Involvement of the testis was found in 35.51 per cent, scrotal fistulas appeared in 41.04 per cent, and pelvic collateral lesions were present in 87.34 per cent. Sixty per cent of the patients suffering from tuberculous epididymitis were known to have renal tuberculosis. It is believed that the prostate is the link in the chain of infection between the kidney and the epididymis, and that the organisms reach the epididymis via the lumen of the vas deferens.

The treatment of choice is surgical removal of the epididymis. When epididymectomy is performed, contralateral vasectomy is advised to prevent

spread of the disease to the healthy side. The local prognosis is good but the general prognosis is that of generalized tuberculosis and is dependent upon conservative therapeutic measures and rest.

CLARENCE V. HODGES, M.D.

Odegaard, H.: On the Treatment of Malignant Tumors of the Testis. *Acta radiol* Stockh., 1945 26 345

In the 10 year period from 1926 to 1935 malignant tumors of the testes in Norway amounted to only 0.3 per cent of the total deaths from cancer in men. From a practical clinical standpoint they may be divided into two main groups: (1) seminomas (2) malignant embryonal testicular tumors. The genitule sarcoma (from the interstitial connective tissue) and the true carcinoma (from tubuli recti) are so rare that they have little significance. Malignant testicular tumors occur with equal frequency on both sides, and usually between the ages of 20 and 30.

The usual treatment today is orchidectomy with postoperative irradiation. It seems to be clear however from the various follow-up examinations published that roentgen treatment of teratomas does not prolong life. On the other hand it is beyond doubt that roentgen treatment of seminomas prolongs life. Hlman has advocated a radical operation, i.e. removal of the lumbar lymph nodes on certain indications. He is of the opinion that patients with teratomas without clinically demonstrable metastases should be subjected to radical operation and maintains that this operation is neither difficult nor dangerous.

If at the time of the orchidectomy lymph node metastases are not demonstrable, it probably does not matter whether the patient receives roentgen therapy or not. In case of incipient spread to the regional lymph nodes one may perhaps have hope of destroying these metastases. On the other hand, if the seminoma metastases have become clinically demonstrable one must count on only a temporary improvement.

At the Norwegian Radium Hospital, from 1935 up to and including 1941 37 cases of malignant testicular tumors have been treated. Of these 21 were seminomas and 16 were malignant embryonal mixed tumors (teratomas). The oldest patient was 71 years of age, the youngest (with a teratoma) 1 1/4 years. In 19 cases the right, and in 18 cases the left testis was affected. The Aschheim Zondek test was carried out in 14 patients with seminomas (all with negative results) and in 11 patients with teratomas, (with a positive result in 1). The reaction was of no prognostic value.

Thirty-four of the 37 patients had been operated on before admission to the hospital. In 3 the condition was inoperable.

Nineteen patients with seminomas and 13 with teratomas have received adequate postoperative irradiation. Of the patients with seminomas, 11 survived and were free from recurrence for 2 years or

more and 8 survived for 3 years or more. 2 have lived for more than 5 years. Of the patients with teratomas, 4 lived free from recurrence for 2 years or more and 3 lived for 3 years or more. Prior to irradiation one of the survivors for 3 years (with a teratoma) was subjected to a radical operation (Hilman's) at which time metastases of the lymph nodes were found.

Nine patients died from metastases within from 2 to 23 months after admission to the hospital and from 7 to 28 months after the onset of the symptoms.

MISCELLANEOUS

Lazarus, J. A.: The Prevention and Treatment of Delayed Wound Healing and Ulcerative Cystitis following Surgery for Tuberculosis of the Genitourinary Tract. *J. Urol.*, Balt. 1946 55: 160.

The incidence of genitourinary tuberculosis has greatly declined within the past two decades.

Postoperative fistula formation and wound disintegration are frequent complications following nephrectomy for tuberculosis.

The ureteral stump plays a negligible role in the production of fistulas.

Sinuses are more apt to occur in the more acute forms of tuberculosis than in the chronic. A combination of deep x ray treatment with ultraviolet radiation immediately following nephrectomy has almost completely eliminated this disagreeable complication and has been found to be an extremely effective method of managing sinuses which are already present.

Of the 63 cases forming the basis of this clinical study, 50.8 per cent revealed cavernous lesions of the kidneys removed, 31.8 per cent pyonephrosis, 8 per cent multiple abscesses, and in 9 per cent the kidneys disclosed the lesions only when sectioned. Bladder ulcerations were present in 63.8 per cent of the cases with cavernous tuberculosis of the kidney, in 45 per cent of the cases of pyonephrosis, in 100 per cent of multiple abscesses, and in 66.6 per cent of the cases in which the kidneys showed lesions only when sectioned.

The average number of x ray treatments given to patients with cavernous tuberculosis was 16.3, with pyonephrosis 13.6, with multiple abscesses 19, and with kidneys showing lesions when sectioned 16.7.

Deep roentgen therapy administered to the bladder is a distinct aid in alleviating bladder pain and in promoting the healing of tuberculous ulcerations.

It is recommended that this type of treatment start immediately after operation, since its greatest advantages are confined chiefly to the prevention of rather than the actual treatment of fistulas already established.

Of the newer agents for the treatment of complicated cystitis following nephrectomy for tuberculosis, the sulfonamides are highly recommended in all cases in which the urine from the bladder shows other organisms besides the mycobacterium of tuberculosis. Calceose, a derivative of creosote, has been found helpful.

A careful course of rigid hygiene, similar to that employed in the treatment of pulmonary tuberculosis, is mandatory in the postoperative management of all cases following operation.

JOHN A. LOEF, M.D.

INTERNATIONAL ABSTRACT OF SURGERY

508

Irradiated with x rays with from 100 to 2,000 r in fractionated doses, moderate filtration long distance and short distance arrangements varying with the case, and the testicles shielded. 3 cases underwent surgery and 2 were both irradiated and operated upon. The results were as follows:

Group	Results
Fully satisfactory	
Nearly satisfactory	
Unsatisfactory	
Not followed up	

Group	Results
Satisfactory	
Less satisfactory	
Unsatisfactory	

The principal beneficial effect was the alleviation of pain during erection which interfered with cohabitation.

The author concludes that radiation therapy should be attempted first the method of application being of minor importance and only if it fails should surgery be recommended.

GREGORY S. SCHWARTZ, M.D.

GENITAL ORGANS

Northwick, W. M.: Tuberculosis of the Male Genital Tract. *Gleason* 11: 3 945 144 173.

The author's discussion of tuberculosis of the male genital tract is centered mainly on epididymitis. The age incidence is essentially that of the period of greatest sexual activity. Of 403 males with tuberculous epididymitis 88.3 per cent had at least one extragenital tuberculous lesion. He does not find that antecedent trauma or nontuberculous infection plays any significant role in the etiology of the disease. Diagnostic signs are induration, enlargement and nodularity of the epididymis, thickening of the vas deferens, involvement of the prostate and seminal vesicles, chronicity and bilaterality of the findings and tuberculous bacillaria. In the differential diagnosis gonorrhea, syphilis neoplasm non specific infection, epididymal cysts, trauma and torsion of the testis, and venous thrombosis of the pampiniform plexus must be excluded. Tuberculous epididymitis was found to be bilateral in 56.47 per cent of the author's cases in lateral in 56.47 per cent was found in 87.35 per cent. Involvement of the testis was present in 87.35 per cent. Scrotal fistulas appeared in 41.09 per cent, and pelvic coincidental lesions were present in 87.35 per cent. Sixty per cent of the patients suffering from tuberculous epididymitis were known to have renal tuberculosis. It is believed that the prostate is the link in the chain of infection between the kidney and the epididymis via the lumen of the vas deferens. The treatment of choice is surgical removal of the epididymis. When epididymectomy is performed contralateral orchiectomy is advised to prevent

spread of the disease to the healthy side. The local prognosis is good but the general prognosis is that of generalized tuberculosis and is dependent upon conservative therapeutic measures and rest.

CLAUDE V. HOBBS, M.D.

Odegaard, H.: On the Treatment of Malignant Tumors of the Testis. *Acta radiol.*, Stockh., 945 26 345.

In the 10 year period from 1926 to 1935 malignant tumors of the testes in Norway amounted to only 0.3 per cent of the total deaths from cancer in men. From a practical clinical standpoint they may be divided into two main groups: (1) seminomas (x) malignant embryonal testicular tumors. The genuine sarcoma (from the interstitial connective tissue) and the true carcinoma (from tubal cells) are so rare that they have little significance. Malignant testicular tumors occur with equal frequency on both sides and usually between the ages of 20 and 50.

The usual treatment today is orchiectomy with postoperative irradiation. It seems to be clear however from the various follow-up examinations published that roentgen treatment of testis tumors does not prolong life. On the other hand it is beyond doubt that roentgen treatment of seminomas prolongs life. Hilmann has advocated a radical operation, i.e. removal of the lumbar lymph nodes on certain indications. He is of the opinion that patients with testis tumors without clinically demonstrable metastases should be subjected to radical operation and mastectomy. It is probably not a very difficult nor dangerous.

If at the time of the orchiectomy lymph node metastases are not demonstrable it probably does not matter whether the patient receives roentgen therapy or not. In case of incipient spread to the regional lymph nodes, one may perhaps have hope of destroying these metastases. On the other hand, if the seminoma metastases have become clinically demonstrable, one must count on only a temporary improvement.

At the Norwegian Radium Hospital, from 1925 up to and including 1941 37 cases of malignant testicular tumors have been treated. Of these, 11 were seminomas and 26 were malignant embryonal mixed tumors (teratomas). The oldest patient was 75 years of age, the youngest (with a testis the left) was 19 years old. The Aachheim-Zondek test was carried out in 14 patients with seminomas (all with negative results) and in 11 patients with teratomas (with a positive result in 1). The reaction was of so prognostic value.

Thirty-four of the 37 patients had been operated on before admission to the hospital in 3 the condition was inoperable. Nineteen patients with seminomas and 13 with teratomas have received adequate postoperative irradiation. Of the patients with seminomas, 11 survived and were free from recurrence for 2 years or

more and 8 survived for 3 years or more 2 have lived for more than 5 years Of the patients with teratomas, 4 lived free from recurrence for 2 years or more and 3 lived for 3 years or more Prior to irradiation one of the survivors for 3 years (with a teratoma) was subjected to a radical operation (Hilomans) at which time metastases of the lymph nodes were found.

Nine patients died from metastases within from 2 to 23 months after admission to the hospital and from 7 to 28 months after the onset of the symptoms.

A careful course of rigid hygiene similar to that employed in the treatment of pulmonary tuberculosis is mandatory in the postoperative management of all cases following operation

JOHN A. LOEY M.D

SURGERY OF THE BONES JOINTS MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Summary T. J., and Pressly C. L.: Sarcoma Complicating Paget's Disease of Bone. *Ann Surg* 1946, 23: 35

Sir James Paget in 1852 saw the first patient with the disease which he later described as osteitis deformans. Altogether he saw 23 cases and his classic description of this spongy hypertrophy of bone is still unsurpassed. It begins in middle age or later is very slow in progress and may give no other troubles than those which are due to the change of shape, size and direction of the diseased bones. It affects most frequently the long bones of the lower extremity and the skull and is usually symmetrical. The bones enlarge and soften, those bearing weight weaken and become unnaturally curved and misshapen. The spine may sink and seem to shorten, but the limbs however misshapen remain strong. But to support the truth, Verchow suggested leontias ossea as a name for the cases in which the disease is limited to the skull and facial bones.

Early in the disease when the connective tissue has replaced much of the original bone, there is bowing of the softened weight bearing bones. As cancellous bone is subsequently laid down in large amounts the cortices become thick and hard and the typical mosaic pattern of lamella develops with fibrous tissue replacing the marrow.

The cause is still unknown but the original acceptance of a chronic inflammation tends to be replaced by the concept of some endocrine cause, the parathyroid seeming to be the most probable offender. Serum alkaline phosphate is high but as yet no other biochemical findings contribute to a solution.

Since many cases of Paget's disease are relatively asymptomatic the incidence rate is dependent upon the extent of the routine roentgenological studies, and may be as high as 10% in 600 patients. Eight of Paget's 23 patients died, his only observation (5 of malignant lesions) and this tendency has been emphasized by many students. Sarcomatous degeneration of bones of Paget's disease is found in from 5 to 40% of the patients according to most authors. The few who question this high percentage still admit a greater incidence than in the general population.

The predisposing factor remains a moot question, but Jaffe's belief that the tremendous proliferative capacity of the tissue involved in polyostotic Paget's disease may in itself be the basic stimulus for tumor formation seems most reasonable. The multiple bone involvement when it occurs is spared lends further credence to this idea. The incidence of osteitis deformans is greatest in patients more than

40 years of age with males apparently predominating among both the cases of the basic disease and those with complicating sarcoma.

To 73 cases of sarcoma complicating Paget's disease collected from the literature, the authors have added their own 3 cases. Localization of the sarcoma favors the femur, humerus, skull and tibia, in that order and the scapula, vertebra, and ilium next most frequently. The prognosis is grave for there is no known cure. Early amputation with or without previous roentgen therapy is the treatment of choice and roentgen therapy alone may be palliative in the terminal stages.

The 3 new cases are presented with illustrative roentgenograms and photomicrographs, which established the diagnosis confirmed at autopsy. A complete bibliography is included.

THOMAS L. BERNACKER, M.D.

Diaz, B. R.: Chronic Tuberculous Synovitis of the Wrist (Sinoitis crónica tuberculosa de la muñeca). *Rev. A. med. argent.* 1945, 50: 17

The cases reported were of the author's own personal experience and are presented because chronic tuberculous synovitis of the wrist does not seem to have been previously reported in the Argentinian medical literature. Also, several aspects of the author's experience seem worthy of special notice. The first was that of a robust officer of the maritime service in whom the bursa of all the tendons on the dorsal and lateral aspects of the left wrist had become progressively involved in a painless swelling with a sensation of rice grain sensation following a blow over this point 5 years previously. The second case was that of a woman of 22 years with a similar history except that there was no known trauma and the process involved both wrists. In her case the duration of the condition was 3 years.

The operation was essentially under Kulenkamp's brachial plexus anesthesia. In the first case and under nerve trunk and peripheral infiltration with novocain (1%) in the second. An incision was made down the middle of the back of the wrist and skin flaps were held back on each side. The posterior ulnar ligament of the wrist (ligamentum carpi dorsale) was incised with apparently a separate incision made directly into each osteofibrous compartment. Each bursa was carefully dissected free down to its attachment to the tendon itself.

In loosening the bursa from the ligament, that portion of the latter which seems badly diseased may be cut away with the bursa, to leave only sufficient tendon substance to assure continuity or if the ligament has lost its continuity it may be reanastomosed by tendon transplantation. It will usually reconstruct itself. An attempt may be made to reconstruct the osteofibrous compartment, although this again seems to be optional as the posterior annular

ligament also shows a tendency to reconstitute itself. The wound surfaces were powdered with iodoform and the skin was sutured to leave merely filiform drainage. The part was put up on a posterior plaster splint for from 8 days to 2 weeks when the stitches and drain were removed and the splint was reapplied with however daily sessions of mobilization of the fingers.

Rich and abundant food, vitamins and calcium were provided and in the second case the condition of the other wrist improved so much following the operation that the projected operation for this wrist was not required.

The author's experience gives one the impression that the lesion reported might be susceptible to tuberculin therapy. JOHN W. BRENNAN, M.D.

Kjelland, P. M.: A Rare Anomaly in the Elbow. *Acta radiol.* Stockh. 1945, 26: 491.

The author presents two cases of patella of the elbow joint.

The first case was that of a washer woman 51 years of age. She suffered two minor injuries to the left elbow, one when a small child and the other at the age of 40, neither of which was treated medically. She also had rheumatism for many years, but with out particular localization to the left elbow. The recent study was brought about by a slight injury to the left elbow 4 days prior to the examination.

Roentgenograms of the left elbow in various views and under different angles revealed what appeared to be a patella of the elbow joint. Under fluoroscopic control this accessory bone was found to move with the olecranon from maximum flexion to the mid position then from the mid position to maximum extension. The upper pole moved forward and finally came to rest with the axis of the patella perpendicular to the axis of the ulna (Fig. 1). Injection of the elbow joint with 20 per cent perabrodil revealed that the contrast medium entered between the olecranon and the anterior aspect of the patella which seemingly was covered with cartilage. In addition there was evidence in this case of arthrosis deformans.

The second case, that of a 73 year old man without a history of previous injury, arrived for examination because of rheumatic pain in the left elbow over a period of several years. Roentgenograms revealed a chestnut shaped accessory bone with a slight concave anterior surface just above the olecranon which was thought to represent a patella of the elbow.

In connection with these 2 cases the author reviewed the medical literature. He was able to collect 15 additional cases. In 11 the diagnosis appeared certain. In the remaining 4, doubtful. In the majority the extension of the elbow was impaired and during movement the bone turned into the fossa of the olecranon as if there was a joint between the posterior surface of the olecranon and the anterior surface of the patella. The posterior surface of the patella serves as a place of attachment for the triceps ligament. Several of the cases re-

Fig. 1. Patella cubiti. The dorsal surface where the triceps ligament is attached the smooth anterior surface which is probably covered with cartilage. Arthrosis deformans, 3 different phases of the joint movement.

viewed showed in addition, characteristic changes of arthrosis deformans. It must therefore be assumed that elbow joints with patellae are predisposed for this affection. Otherwise the symptoms are few and patients afflicted with it are able to work.

The etiology is not altogether clear. The author prefers to assume an embryonic origin for several reasons. It is known that the olecranon sometimes has two points of ossification, one of these develops into the olecranon process of the ulna and the other into an accessory olecranon. By the same mechanism the second point of ossification may develop into a patella of the elbow joint. The origin from a pseudarthrotically healed olecranon fracture as advocated by others is contradicted by the fact that in only 2 of the reviewed cases was there evidence of definite trauma. Moreover in 4 cases the condition occurred bilaterally and in 1 instance it was found in father and son. Finally there is ample proof that patella of the elbow joint is encountered in the animal kingdom, for example in frogs and lizards, in birds, bats, insect eaters, rodents, and one of the edentates.

T. LUCUTIA, M.D.

Lapidus, P. W.: Spastic Flatfoot. *J. Bone & Sw. Surg.* 1946, 28: 126.

Painful so-called spastic rigid or contracted flat foot is a clinical entity vaguely described in most textbooks. Most investigators have believed that the condition is an advanced phase of flaccid flatfoot wherein faulty mechanics set up a reflex spasm of the plantar muscles because of irritation in the subtalar region.

A review of the literature presents no more apt conclusion than those voiced by Todd who offers a concise summary of the present state of our ignorance and agrees with the present author's belief that treatment of the spasm alone is not rational. Spasm is not the disease but the result of the disease and manipulation with immobilization in various plantar physiological positions, the valgus position being a position of rest for the involved joint.

It is generally agreed that the condition is painful with spasm limited to the pronator group. Trauma or occupational strain is noted appreciably often. The onset frequently occurs during adolescence. The incidence is slight compared to the large number of flaccid flatfeet seen. There are various interpretations of the facts that pes planus is not always present and that a normal or even cavus condition of the longitudinal arch may concur. Tenderness has been noted both on the lateral and medial aspects of the foot. The role of arthritis of the subtalar joint is variable.

The author presents the anatomy and mechanics of the subtalar joint graphically and gives a logical explanation for the pronator spasm. Any lesion of the interosseous talocalcaneal ligament, regardless of etiology, may induce the syndrome appropriately called "spastic subtalar lesion." The subtalar joint surfaces may or may not be involved and pes planus is not necessarily a part of the syndrome.

The author classifies cases of the disorder according to the extent of the pathological changes, and outlines the treatment appropriate for each type. Drastic procedures aimed at the elimination of pronator spasm are unsound and often dangerous.

FRANCES E. BISHOPWECK, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Higgs, S. L.: The Use of Cancellous Chips in Bone Grafting. *J Bone Surg* 94b 33 5.

Seventy-one consecutive cases of bone grafting were reviewed by the author 63 of which were operations for nonunion of the long bones. Among the latter group, cortical grafts alone were used in 20 cases and cortical grafts plus cancellous chips were used in 40 cases. All of the operations resulted in union, although in 4 patients reoperation was required.

The 10 other cases were osteoclastomas, solitary cysts and osteitis fibrosa cystica, and arthrodeses, in all of which cancellous chips were used to fill the bone defects.

For successful use of cancellous chips, rigid fixation is necessary. The author has used a screwed-on onlay graft for the humerus, an onlay or inlay for the radius and ulna, a sliding inlay or onlay from the other leg for the tibia, and a screwed-on onlay graft for the femur.

Sclerosed bone must be removed as well as all scarred and fibrous tissue. Bare muscles should be brought in contact with the bone whenever possible. Skin grafting may be necessary.

Despite the fact that many of the cases had recently been septic, bone grafting was done. Penicillin and sulfanilamide powder were applied.

Bone chips hasten the time of union by approximately 5 per cent. The chips with cortical grafts add in filling gaps in the long bones and defects in cysts and in filling gaps and crevices in arthrodesis operations.

DANIEL H. LEVINTHAL, M.D.

Ernst J.: Canalization of the Femoral Epiphysis According to Duverney (Le forage de l'épiphyse fémorale de Duverney). *Acta radiol* Stockh 1945, 36 76.

Duverney popularized drilling of the femoral epiphysis as the method of treating arthrosis of the hip. For this purpose he uses a drill 6 mm. in diameter which makes a channel through the femoral neck and head.

Contradictory opinions regarding the mode of action of the operation have been advanced by various authors. Some claim that the procedure is followed by a diminution of the hyperemia which is responsible for rarefaction of the bone. This hypothesis is based on oscillographic measurements which show larger excursions before than after the operation. Others maintain that the hyperemia following the operation produces granulations of the bony structures. This result is compared with the sequelae of drilling the bone in cases of pseudarthrosis.

Results of the operation reported by various authors differ to a great extent. This may be due to variations in the length of observation or to differences in the pathological conditions. From the anatomopathological point of view some writers differentiate two types of arthrosis of the hips: (1) the sclero-osteophytic type in which sclerotic bone tissue and cysts are found (this type has a slow evolution and limitation of motion is more pronounced than pain) (2) the type which is characterized by atrophic alterations and rarefaction. In the latter type osteophytic formations are soft, and the osseous rarefaction and formation of cysts are marked. The cysts, contrary to those in the first type, are not surrounded by sclerotic tissue; they are soft and compressible. The lesions develop rapidly and cause much pain. This type of arthrosis yields the best results after drilling.

The author performed canalization of the femoral epiphysis 41 times in 30 patients, 2 of whom were treated on both sides. The drill used was 5 mm. in diameter. In the majority of the cases several canals, up to 8, were drilled; the average number being 3 or 4. Of the 41 operations, 19 were done in women and 22 in men. The lesion was present on the right side in 23 instances and on the left side in 18. The ages of 19 patients ranged from 31 to 60 years; of 11 from 61 to 70 years; of 6 from 41 to 50 years; of 3, from 31 to 40 years; and of 2, from 71 to 80 years. The duration of symptoms in 5 of the patients exceeded 5 years. In 33 cases the condition was primary ilio-patitic, and in 8 it was secondary following a contusion of the hip, fracture of the femoral neck, congenital dislocation, or coxa vara.

As to the complications, 2 patients developed a hematoma, 2 developed phlebitis, 1 pneumonia, and 1 paresis of the peroneus muscle. In 4 patients a tenotomy of the adductor muscle was performed immediately following the drilling or a few days later.

A follow-up of 6 months after the operation showed the condition to be improved in 76.4 per cent and

unchanged in 23.6 per cent the respective figures after two years were 70.1 and 29.9 per cent, and after six years 64.3 and 35.7 per cent, respectively. After six years 53.6 per cent of the patients had no pain at all, while in the remaining 9.7 per cent of improved cases the amelioration was partial as far as pain and limitation of motion were concerned.

In cases favorably influenced by the operation the cysts and osseous rarefaction subsided to a great extent, being replaced by a solid tissue while in cases in which failure was recorded, sometimes an increase of the number of cysts and rarefaction of bone were found. The operation apparently was not followed by a diminution of the osteophytic formation or decrease of deformity of the femoral head in either group.

JOSEPH K. NARAT, M.D.

FRACTURES AND DISLOCATIONS

De Luca, G., and Farina, M. G.: *The Treatment of Compound Fracture and the Closed Plaster Method* (La cura delle fratture esposte ed il metodo degli apparecchi gessati chiusi). *Polidina* (1st part) 1945 54 403.

The closed plaster method used by the authors in both civilian and military practice for compound fracture is essentially that developed by Orr and later by Trueta, the circular plaster cast being applied directly to the skin according to the principles laid down by Boehler following the first World War.

In the authors' own material consisting of 1,886 open fractures 151 cases occurred in civilian life and 1,735 were due to war. The closed plaster method was used in 137 civilians (90 per cent) and in 1,320 soldiers (76 per cent). In civilian practice good results were obtained with this method in 78 per cent of cases, mediocre results in 10 per cent, and poor results in 12 per cent. In military practice good results were obtained in 73 per cent, mediocre results in 13 per cent, and poor results in 15 per cent. However the slightly higher percentage of unsatisfactory results in military practice is not a fair comparison because of the higher percentage of serious fractures. For instance there were four times as many leg fractures as those of the femur in civilian patients while in the military material fractures of the femur predominated markedly. Primary soft tissue suture could be done in 112 of the civilian patients, but was not attempted in the war material. In civilian practice there was not 1 instance of gas gangrene or of tetanus while there was a single example of each in the war material.

The case with tetanus, an open fracture of the lower third of the right leg was of especial interest in that the patient was erroneously twice given tetanus antitoxin on succeeding days immediately after the injury on the tenth day there were clear indications of tetanus infection, which however disappeared under the usual therapy.

The authors' primary treatment of the wound which they call mechanical sterilization and which

they seem to distinguish from excision of the wound, consists of freeing the wound from blood clots, all foreign material, and devitalized tissues especially muscle tissue and detached bone splinters. It is initiated—if the condition of the patient permits—under intravenous eunarcosis anesthesia after 1 or 2 hours in order that the patient may recuperate from any initial shock. An attempt is made to bring the blood pressure to about 110/65 and diagnostic or other manipulations of the injured part are kept to the minimum. At this time an attempt should be made to appose the bone fragments before they are incased in the plaster and even in the cleanest wound perhaps with primary suture sulfa drugs should often be insufflated into the wound.

The surgeon must first be assured of the vitality of the limb with extension in a Thomas or Braun splint (perhaps for a few hours at first) and close watch must be maintained at all times during the succeeding days. In fact it may at times prove hazardous to enclose the limb of a wounded man in plaster in wartime if he must be transported immediately and transferred to the care of other surgeons who may not be aware of the importance of the lesion.

JOHN W. BRENNAN, M.D.

Kirby, C. K., and Flitt, W. T., Jr.: *The Incidence of Complications in the Use of Transfixion Pins and Wires for Skeletal Traction*. *Ann. Surg.*, 1946 123 27.

At a General Hospital in India, 342 transfixion pins and wires (195 Kirschner wires, 95 Steinmann pins and 52 Roger Anderson pins) were used in the treatment of 333 fractures of the long bones. Three hundred and five pins and wires were observed during the entire period of their use and were removed at the hospital.

Among the 305 transfixions there were 12 complications as follows: soft tissue infection without osteomyelitis or the formation of a chronic draining sinus at the site of a Steinmann pin; loosening of 4 Kirschner wires; loosening of 3 Roger Anderson pins; 2 cases of transient peroneal nerve palsy; breaking of 1 Kirschner wire and slipping of 1 Kirschner wire bow. It is believed that the last 11 complications were avoidable, and in no case did a complication have any significant effect upon the course of treatment or the final result. The final results of treatment are not described in the article.

After an observation period of from 5 to 6 weeks there were no complications in the 37 transfixions in which the final result was unknown. Prophylactic sulfa drugs were administered to approximately 60 per cent of the patients either because the fracture was compound or because of associated injury or disease and no infection developed in this group. Since infection occurred in only 1 of the 40 per cent of patients who had not received sulfonamides and it is not at all certain that a sulfonamide would have prevented this infection, there is no statistical evidence that prophylactic sulfonamides played a part in preventing infection at the pin site.

in this series. In no instance was a prophylactic sulfonamide used for the sole purpose of preventing infection at the pin site.

CHARLES A. WATMAN, M.D.

Robertson, R. C., Cawley, J. J., Jr., and Faris, A. M.: The Treatment of Fracture Dislocation of the Interphalangeal Joints of the Hand. *J Bone Surg* 94b 58 68

Fracture dislocation of an interphalangeal joint of the hand is an uncommon injury and in the absence of adequate treatment results in severe permanent disability. Reduction is difficult to maintain by conservative methods of splinting, because of pressure necrosis of the soft tissues and the authors recommend a method of multiple skeletal traction which they employed successfully in the treatment of 7 cases of this type.

The finger is prepared for surgery and is covered with a sterile dressing. A plaster-of-Paris cast is applied from the proximal palmar crease high onto the forearm and a wire banjo splint is incorporated in the desired position. Under general or local anesthesia a small Kirschner wire is inserted transversely through the neck of the phalanx proximal to the dislocation and another wire is placed transversely through the base of the phalanx distal to the dislocation. A third wire is passed transversely through the neck of the middle phalanx if the injury involves the proximal interphalangeal joint. If the distal interphalangeal joint is involved the third wire is passed transversely or vertically through the distal phalanx. A small temporary dressing is applied about each protruding wire. The wire is then cut and fashioned to form a traction bow. To each of the bows a rubber band is attached and fixed to the banjo. The involved joint is then flexed to from 30 to 30 degrees and the desired traction is applied to each band at such an angle as to secure reduction of the displacement.

In the 7 cases treated by the authors the shortest period of traction fixation was 2 days and the longest was 30 days. There were no operative infections and excellent functional results were obtained. All 7 cases reported were caused by the patients being struck on the end of the extended finger by a baseball or softball. CHARLES A. WATMAN, M.D.

Soto-Hall, R., and Horwitz, T.: Compound Fractures of the Femur. *J Am Med Ass* 94b, 3 28.

The late results of treatment of femoral fractures are reviewed in an attempt to throw light on the etiology of such complicating factors as sepsis, nonunion, deformity and knee stiffness. The series includes 17 compound fractures of which 7 had been treated by early internal fixation. To obtain the proper standard for comparative study, 46 simple fractures are included of which 24 had been treated by early internal fixation.

A very high proportion (80%) of compound fractures without internal fixation healed without

sepsis. When this group is added to the 44 per cent classified as mild infections because they represented mainly soft tissue sepsis and healed within 5 to 8 months, the whole picture presents a brilliant achievement of war surgery.

The infected fractures (17%) include many cases of extensive loss of soft and bony tissue with vascular damage in which sepsis is almost unavoidable. In cases treated by early internal fixation through an open wound, the incidence of severe sepsis was about 50 per cent higher than in patients treated without metal fixation. In the cases of most of these men the plates or metal had to be removed. In some cases severe infection appeared to be under control for several weeks while chemotherapy was being administered later the infection became clinically evident.

The following procedure seemed to offer the least danger for the type of fracture in which internal fixation appeared indicated.

A thorough débridement was done early, and was followed by delayed closure of the wound from 7 to 10 days later. After the original wound had healed in an average of 6 days the fragments were approximated through a separate longitudinal incision and held together by metal fixation. In some types of fracture the use of screws has given better results than the plate probably because of less surgical trauma.

Chemotherapy included the use of penicillin or a sulfonamide compound, or both. The findings confirm the fact that modern antibacterial agents may produce excellent results in the control of infection and in the reduction of complications, but that they are impotent in the presence of tissue which has lost its blood supply and which does not allow the drug to come in contact with the infection.

Cases in which union occurred within a period of from 5 to 7 months were classified as delayed union cases showing neither clinical nor radiological evidence of bone union beyond 7 months were classified as having reached the stage of nonunion. Considering the frequency of severe injury with comminution and absence of bone fragments, the proportion of bone union which occurred in cases treated by external splinting was extremely high, 86 per cent and definitely higher than the finding in fractures treated by internal fixation. A comparison of the time required for union in simple fractures treated by open and by closed methods demonstrates that in spite of the improved apposition of fragments in the open cases, there was little difference in the period needed for bone healing. The state of delayed union and of nonunion appears directly related to the degree of bone loss or damage, distraction and the presence of infection. Distraction even of a very minimal amount, is particularly harmful.

A comparison of the results with respect to restoration of knee motion in men treated by internal fixation and in men treated by traction showed no appreciable difference. The findings were not en-

tirely conclusive because in a number of patients who had had repairs or delayed union the splinting had been too recent. The average period from the date of injury to the last examination was only 9½ months so that the statistics do not indicate the final result but do describe the slowness in restoration of joint motion. Two factors which were found to be definitely helpful were the use of restative exercises and the use of delayed closure. Successful delayed closure resulted in much earlier healing and less scarring so that exercise and activity could be started earlier. An important disability was a limitation of extension of from 5 to 10 degrees in about one-third of the cases. This disability could be overcome after several weeks of active exercise, but its occurrence argues in favor of treatment of fractures above the lower third with the knee in full extension.

Other complications were refracture in 5 patients and renal lithiasis in 6 patients.

The authors conclude that early and adequate débridement is the most vital factor in the successful treatment of compound wounds and that conservative treatment of traction in balanced suspension gives extremely gratifying results.

JOHN L. LINDQUIST M D

King, T: Slowness and Failure of Bony Union after Fractures and Osteotomies of the Proximal or Trochanteric End of the Femur. *Austral N Zealand J Surg*, 1945 15 33

Nonunion is very rare in extracapsular lateral or intertrochanteric fractures of the femoral neck and low union is the rule. In the past 10 years the author has seen only 2 cases of nonunion of fractures of these types. Prolonged immobilization provokes complications and difficult nursing problems which may be obviated by internal fixation by the Blount and Moore blade apparatus the nail and plate method of Jewett or Hawley and other similar methods. In addition more rapid osseous union results because of good reduction firm apposition of the fractured surfaces and absolute immobilization. The Stader or any other form of splinting which requires that the bones be transfixed by ¼ inch nails above and below the fracture site and attached to some form of external holding apparatus is considered too dangerous because of the infection along the pins that must inevitably occur in a certain proportion of cases.

Fractures at the base of the neck and between the tip of the greater trochanter and lesser trochanter can be treated with the Smith-Petersen nail and no supplementary plate is required. When the fracture is situated distal to the level of the lesser trochanter a plate is attached to the Smith Petersen nail. In the reduction of fractures of this type, coxa vara should be overcome on the orthopedic table by traction and abduction but the external rotation that is present in most cases should not be corrected by internal rotation of the limb as is carried out in intracapsular fractures. Accurate reduction is ob-

tained by allowing the limb distal to the fracture to remain externally rotated about 45 degrees from the vertical plane and thereafter correcting any differences in the angles of rotation between the fractured fragments by pulling forward the trochanteric fragment with a sharp hook. When the nail is introduced the angle of declination is forward from 25 to 45 degrees instead of backward. At least 1 to 1½ inches of the head end of the nail should stand out before the plate is attached, as it will be impossible to attach the plate if the nail is driven all the way in. A modified Hawley plate with a reamed ring is used and is attached to the tapered head of the nail. It provides a strong fitting especially when fixed down by the screw. When the angle between the plate and reamed ring is to be altered so the plate is parallel with the femoral shaft another taper headed nail should be used for the adjustment while the plate is held in a sterile towel. Levers, pliers, or vises should not be used to alter this angle as they may convert the absolute circle of the reamed ring into a slight ellipse and thereafter it will not be possible to attach the ring to the tapered nail head.

Seven cases of nonunion among 120 subtrochanteric osteotomies are reported and summarized according to Table I. Three cases were treated by bone grafting. The pelvis is raised 6 inches from the operating table with sand bags. At least half of the iliac crest and adjacent ilium should be removed to obtain a sufficient amount of bone for packing the ununited bone area. The site of nonunion is approached by an incision that is somewhat more anterior than the usual lateral one. After the bone is exposed by cutting through the tensor fascia femoris and vastus lateralis muscles, a curved lever is placed medial to the femoral shaft and just below the base of the calcar femorale in the region of the lesser trochanter. Thereby the nonunion area is seen from the front. A ½ inch gouge is used to cut a gutter in the bone proximal and distal to the ununited area and this gutter should be as large as possible. The gouge is driven deeply into both fragments so that bleeding cancellous bone is exposed. The fresh bone obtained from the ilium is chopped up bone pieces no larger than maize. The chopped up bone is hammered into the medullary cavities of both fragments of the nonunited bone with the blunt and round head of a chisel until it forms a paste. After that the bone is packed in front and to the lateral side. Finally any respectable looking bone that had been cut out of the ununited area for providing the gutter is chopped up into chips about the size of wheat grains and inserted. When the wound is closed a bulge should be evident on the surface, indicating that a large mass of bone grafting material lies underneath. Immobilization is done by means of plaster spica or with the sling and traction. All 3 patients operated upon obtained sound osseous union.

The method was also used successfully in the treatment of a patient with nonunion following a fracture of the upper femoral shaft a trochanteric fracture

TABLE L—ANALYSIS OF SEVEN PATIENTS WITH NONUNION OUT OF ONE HUNDRED AND TWENTY SUBTROCHANTERIC OSTEOTOMIES

No.	Reason for Osteotomy	Age	Type	Post-operative Splinting	Treatment of Nonunion by Bone Grafting	Splinting after Bone Grafting	Result of Bone Grafting
	Osteoarthritis	63	Loruss Mc Murray 3/10/40	Slit and traction	None	—	—
	Osteoarthritis	1	Schana 12/12/43	Large spica	None	—	—
3	Osteoarthritis	33	Schana 4/11/43	Slit and traction	10/3/43	Large spica	Osteous union
4	Nonunion of fractured neck femur	40	Loruss Mc Murray 4/1/44	Slit and traction	None	—	—
5	Nonunion united fractured neck femur	51	Loruss Mc Murray 1/11/43	Large spica	None	—	—
6	Osteoarthritis	5	Loruss Mc Murray 7/1/43	Large spica	20/7/44	Slit and traction	Osteous union
7	Congenital dislocation of hip	33	Schana 2/2/43	Slit and traction	10/4/44	Large spica	Osteous union

() Ninety patients were immobilized by slit and traction, and 10 in large plaster spica. () There were 3 patients with nonunion and 4 of these had been immobilized by slit and traction and 1 by plaster spica. (3) Three of the 7 patients with nonunion were operated upon by bone grafting, and osteous union resulted.

In the presence of infection an advantage of this type of bone graft is claimed over the tibial twin saw bar of bone because the entire graft is not prone to be lost. Case 6 had a sinus which could not be cleared up. It was excised at the operation and the spongy bone graft was employed. Infection super-vened, but osteous union resulted after 6 months. When spongy bone graft for nonunion is combined with nailing and plating the nail and plate are attached first. The front aspect of the femur is guttered at the fracture site and not on the lateral aspect. A complete freeing of the two ununited ends is unnecessary. It takes too long and is harmful because it results in a disturbance of the blood supply.

Internal fixation of the osteotomized fragments after subtrochanteric osteotomy by nailing and plating eliminates external splinting and the patient may be ambulant or at least free to move around in bed. Before the operation, the exact site, line, and angle of the osteotomy must be planned because of the bends and angles that must be made in the plate to conform to the osteotomy. These details are worked out with paper models made from tracings of the x-rays. The plate is bent by the surgical

maker to the shape required because the steel must be heated for bending. The plating of a Loruss McMurray osteotomy is fairly easy if the plate is bent beforehand and the osteotomy is performed to plan, but the Schana operation is more difficult unless the upper fragment can be hooked down into the adducted position. If it cannot, then the leg must be fully abducted below the site of osteotomy which will make the application of the plate rather difficult.

Primary subtrochanteric osteotomy has been substituted by some surgeons for nailing of intra capsular fractures of the femoral neck to eliminate nonunion or traumatic arthritis because it is the method of treating these complications should they occur. The author suggests combining nailing and plating with primary subtrochanteric osteotomy if the fracture is more than 3 weeks old, the bone is comminuted, or the patient is a young manual laborer. No cases utilizing this form of treatment are reported.

This article is well illustrated with diagrams and x rays. A short bibliography is appended.

CHARLES A. WALKER, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Ross, J. P.: The Surgery of Arterial Disease and Injury *Brit. M. J.*, 1946 1: 1

Vasospastic phenomena are seen in a variety of conditions but true Raynaud's disease is a clinical entity. It is characterized by color changes in the digits produced by cold and occurring in attacks which show a rapid onset and recovery, the extremities are affected symmetrically. The peripheral pulses are preserved, and if there is any loss of tissue it is never more than a shallow ulceration close to the fingertips. True gangrene is extremely rare. The condition is almost exclusively limited to females, is not commonly excited by emotion and is not usually associated with excessive sweating. The author agrees with Lewis that it is due to abnormal sensitivity to local cooling of the small arteries.

In an attack the lumen of the digital arteries is almost completely obliterated. The value of sympathetic denervation is that the lumen of the vessels is permanently increased so that a cold stimulus while reducing it greatly does not arrest the circulation completely. Since sympathectomy should be complete for satisfactory results the author favors the posterior approach of Southwick and White for the upper thoracic chain. With the anterior approach of Telford there is greater danger of sparing anatomically abnormal filaments. For the lower extremity removal of the second, third and fourth lumbar ganglia is the usual procedure.

While there are many different causes of obliterative arteritis it is the level of the block in the arterial tree, not the cause, which determines the clinical picture and the value of sympathectomy in its treatment. Three clinical groups may be recognized. In one, a main vessel, such as the femoral or popliteal artery is thrombosed and the presenting symptom is intermittent claudication in the calf muscles. The nutrition of the skin of the foot remains good since an adequate collateral circulation keeps the distal vessels supplied. If the level of the block is low enough to involve the sural arteries which supply the gastrocnemii sympathectomy is of little value for claudication. However if the block is more proximal sympathectomy will provide a considerable increase in the blood flow to the calf. For this reason it is important to palpate the femoral and popliteal pulses as well as those in the ankle.

Some information about the probable effect of sympathetic denervation may be obtained by temporary block of the sympathetic trunk. A good response is an argument in favor of operation. On the other hand a poor response is not sufficient to deny the patient possible relief by sympathectomy since the postoperative improvement is gradual.

In the second clinical group the distal arteries are principally affected and the characteristic mani-

festations are rest pain and nutritional changes in the skin of the foot. The pulse in the main vessels may be present even at the ankle but there is an abrupt drop in the surface temperature at the level of the arterial obstruction. Sympathectomy in this group may often abolish the intense pain and permit successful local amputation of the toes if gangrene has already been established.

In the third group there is widespread narrowing of the lumen throughout the arterial tree. Sympathectomy is generally useless and amputation above the knee becomes necessary.

Fresh lacerations of the arteries should be repaired when possible, but contusions should be treated by excision of the contused segment and ligation of the companion vein. When an arteriovenous fistula follows vascular injury quadruple ligation and excision is the usual operative procedure. Twice in cases of popliteal aneurysmal varix the vein was ligated above and below the fistula so that the latter could be isolated and ligated like an arterial branch. The main artery was preserved. These patients suffered from symptoms of venous obstruction afterward. Consequently, in 2 other cases the artery was ligated above and below the fistula but the vein was left intact; the results were most satisfactory in these 2 patients. Because of the abundant collateral circulation associated with arteriovenous fistulas it is advantageous to preserve the vein when it is feasible to do so.

THOMAS B. MARSHALL, M.D.

BLOOD TRANSFUSION

Iokhveda, B. I.: Intracardiac Blood Transfusion *Amer. Rev. Series M.* 1945 212 216

The author reports 3 cases in which a physiological solution of sodium chloride, glucose, and blood were used for restarting the intracardiac blood flow.

In the first case the transfusion of blood through a needle inserted into the right ventricle corrected the apparent or clinical death and restored consciousness. Severe myocardial damage was probably responsible for the irreversible death that occurred 3½ hours later. It should be emphasized that in spite of the marked flabbiness of the myocardium the needle which was present in the heart for about 15 minutes while the heart was contracting had left only a minute puncture.

In the second case the cause of collapse and clinical death may be attributed to the profuse hemorrhage and to the rapid blood loss. A reflex shock occurred the volume of the circulating blood decreasing even more and the flow of blood to the heart diminishing greatly. Application of massage to the heart externally and the intracardiac injection of epinephrine might be insufficient in such cases since the cause of death is not failure of the myo-

cardium but inadequacy of the blood supply to it. The heart even when revived, will continue to work in vacuum and after a few seconds or minutes will stop again. Therefore, the author decided to adopt a more physiological approach by increasing the contents of the cavities. It is known that an increase in the contents, although not maximal is an adequate impulse to start contraction, as long as the heart is capable of responding to stimulation.

In the second case injection of blood and salt solution into the left ventricle rather than the right was indicated for a definite reason. Insufficient contracting force of the recently revived heart and the pressure behind the injected solution would have been insufficient to overcome the resistance provided by the capillary network in the lungs and only insignificant amounts would have reached the left side of the heart. By injecting these solutions directly into the left ventricle even the first and comparatively weak contractions of the heart re-established the blood supply to the vitally important brain centers and thus provided an antishock effect. In addition the increased volume output of the left ventricle independently improved the coronary blood flow.

When blood and other liquids are to be transfused into the right chamber the needle should be inserted into the lower part of the fourth left intercostal space one finger's breadth from the left margin of the sternum. This site will prevent injury to the intercostal neurovascular bundle and the internal mammary artery. The left ventricle will be entered when the needle is inserted in the same intercostal space and from 2.5 to 3 cm. to the left of the left margin of the sternum. *Joaquin Garras, M.D.*

De Weerd, W.: The Influence of Sex in Transfusion Reactions (Influence du sexe sur les réactions transfusionnelles). *Rev. belge de méd.* 945: 6, 1934.

Attention is directed to the role of the sex of the donor and of the recipient in the incidence of transfusion reactions. De Montla and Delhaye in 1937 found transfusion reactions in 8.7 per cent of female to female transfusions, in 8.3 per cent of male to female, in 3.9 per cent of female to male, and in 3.5 per cent of male to male. Hustin and Remy in 1942 studied 864 transfusions, and found transfusion reactions in 17.3 per cent of female to female transfusions, in 9.1 per cent of male to female, in 6.3 per cent of female to male, and in 5.3 per cent of male to male.

The author has compiled data on 666 transfusions given by the Belgian Red Cross in 1933 and has grouped them according to the sex of the donor and the recipient as follows:

	Transfusions	Reactions	Percentage
Female to female	88	28	3.2
Male to female	5	35	3
Female to male	90	43	
Male to male	37	47	9.8
Total	666	5	8

When grouped as to transfusion indications (neoplasms, infections, anemias) more reactions occurred in the patients who had primary blood dyscrasias.

The author believes that more research is necessary to determine the significance of the sex of the donor and of the recipient in transfusion reactions.

C. Farnsworth Ketter, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Croce, E. J. Schullinger R. N. and Shearer T. P.
The Operative Treatment of Decubitus Ulcer
Ann Surg., 1946 123 53

The authors present a method of primary closure of decubitus ulcers in young paraplegic casualties. Given the same back care postoperatively as the paraplegic without bed sores, the results seem to be quite as satisfactory as in patients with unbroken normal skin. The method seems to be applicable to the largest sacral ulcers. With rare exception, the results may be obtained by a single stage procedure. Careful pre-operative preparation and evaluation are just as important as is the technique of the operation itself.

The operation is performed without anesthesia. Complete excision of the ulcer including the peripheral scar tissue and the base is essential. Curvilinear incisions are made on each side of the defect and flaps are raised sufficiently to close the excised area. This is done by rotating the flaps on each side toward each other. Fine nonabsorbable sutures are used. Postoperatively pressure dressings are applied. Penicillin and sulfadiazine are administered when indicated.
BRYJAN GOLDMAN, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Dunroch, D. S.: Chemoprophylaxis. *J Am M Ass* 1946 130 124

In November and December of 1944 a controlled program of chemoprophylaxis against hemolytic streptococcus infections which were then of epidemic proportions was employed in three small naval training schools.

In the month of November significantly fewer streptococcal infections occurred in the groups receiving sulfadiazine prophylactic treatment (in daily doses of 1 gm.) than in the control groups. During this period sulfadiazine resistant Group A beta hemolytic streptococci were absent in one school and present only in small numbers in the other two schools. In December however with new trainees there was a progressive failure to prevent streptococcal infections in the treated group. The failure was related to the increasing prevalence of strains of Group A hemolytic streptococci which showed resistance to sulfadiazine in vitro.

WALTER H. NADLER, M.D.

Ackman, D. and Smith F. The Role of Chemotherapy in Wounds and Surgical Infections.
J Am Surg 1946 123 70

For the past 2 years the authors have been jointly engaged in a study of the effect of bacteriostatics in fresh trauma and pre-existing infections for the

National Research Council of Canada. The object of this investigation has been to determine as far as possible the practical value of bacteriostatics used topically or systemically and both prophylactically and therapeutically in fresh trauma and pre-existing infections. The work has been done in civilian hospitals and the laboratories of McGill University. A uniform surgical technique was adapted to the individual case so that the chief variables were the type of bacteriostatic and method of application.

The following points summarize the authors' convictions.

The nature, age and extent of any injury or infection profoundly modify the value of any anti-biotic substance.

Adequate surgery is more essential in the treatment of trauma than are chemotherapeutic substances.

The mere presence of bacteria in a wound is by no means synonymous with infection.

Bacteria tend to persist in a healing wound up to the time of complete and final epithelization without clinical signs of infection.

Pyogenic streptococci regularly disappear from wounds and pre-existing infections treated with sulfonamides or penicillin. Most other wound pathogens, notably the staphylococcus pyogenes, bacillus proteus vulgaris, pseudomonas pyocyanea, and clostridium welchii, persist in the presence of chemotherapy without necessarily producing clinical infection.

Bacteria in wounds were a far greater hazard in presulfonamide days than at present despite our inability to sterilize a wound completely.

Topically applied penicillin has not proved as effective an agent as sulfathiazole probably because of its rapid disappearance which makes frequent exposure of the wound necessary. Its routine systematic use in a large ward with normal personnel is much more burdensome than that of the more convenient sulfonamides.

It seems certain that bacteriostatics keep the contaminated wound from becoming an infected wound. Thus they probably do by prolonging the important lag period restraining free bacterial multiplication during this time and allowing elaboration of the natural barrier to microbial invasion.

All this is facilitated by immobilization and occlusive compression dressings which are changed infrequently.

Hypersensitivity reaction from topically applied sulfonamides is a highly controversial issue. The authors have seen such little evidence of it with infrequent dressings that they consider the risk entirely unimportant.

There is no convincing evidence that the bacteriostatics which have been used significantly influence

the pseudomonas pyocyanea or bacillus proteus vulgaris in a wound. This remains one of the outstanding unsolved problems. Both the unreserved condemnation of bacteriostatics and their endorsement as "miracle drugs" are the results of completely uncritical judgment. The truth as usual, lies somewhere between these two extremes. As far as trauma is concerned the most efficient of the bacteriostatics is, at best, only an adjunct to adequate surgery.

In chronic surgical infections surgery and amputation are interdependent. In acute spreading infections, chemotherapy is the immediate necessity.

BENJAMIN GOLZMAN, M.D.

Meleney, F. L., Johnson, B. A., Polsky, E. J., and Colonna, F. The Treatment of Mixed Infections with Penicillin. *J. Am. Med. Ass.* 946 30

In the treatment of surgical infections with penicillin it is of the utmost importance to have a complete picture of the bacterial flora of such infections and to know whether the organisms present are susceptible, indifferent, or antagonistic to penicillin. Attempts should be made to eliminate aerobic gram negative, nonsporeforming bacteria, which have a destructive action, before susceptible species have developed resistance to penicillin.

p-chlorophenol is the most effective antibacterial agent against gram negative organisms, of the presently available antiseptics so far tested. In a concentration consistent with safe clinical application p-chlorophenol was bacteriostatic and bacteriocidal for all the gram negative organisms tested whereas o-aminocidine hydrochloride and 5 nitro 2 furaldehyde semicarbazones were not effective against the pseudomonas pyocyanea.

The individual strain susceptibility of the gram negative organisms isolated from any given infection should be tested for the inhibitory action of para-chlorophenol, o-aminocidine 5 nitro 2 furaldehyde semicarbazone streptomycin and streptomycin, since the sensitivity of different strains within the same species as well as the sensitivity of different species varies greatly. All of these agents are compatible with penicillin and may be combined for local application to infected wounds. They may be incorporated in a carbonyl propylene glycol base for topical application and prolonged action in wounds.

W. T. H. NADLER, M.D.

Lescock, A.: Penicillin for Chronic Undermining Ulceration. *Bull. M. J.* 945 765

The case reported here is that of a 32 year old soldier who developed a large abscess in the left arm following an injection of T. A. B. vaccine. Despite free incision and drainage abscess pockets occurred and had to be incised. Undermining of the edges took place with the typical zones about the edges described by Meleney. The edges were excised and the sinuses opened to give a large flat wound. Plaster immobilization for one month resulted in a grad-

ual extension of the ulcer so that the involved area covered most of the posterior surface of the arm. Various bacteriostatics were unavailing. Zinc peroxide was not obtainable. An anaerobic hemolytic streptococcus staphylococcus aureus and pseudomonas pyocyanea were isolated from the wound on culture.

Seven and one-half months after the initial injection the lesion was treated with local penicillin (100 units per cubic centimeter) enough to keep the dressings wet. After 48 hours the penicillin sensitive organisms had disappeared and in 5 days improvement was marked. The pyocyanea diminished under 1 per cent acetic acid dressings. Epithelialization covered more than half of the area and Thiersch grafts were applied to the remainder.

The literature is discussed and the lesion is demonstrated from postoperative cutaneous gangrene. The author believes that penicillin applied locally may be more effective than zinc peroxide and may replace it.

THOMAS C. DOUGLAS, M.D.

Wu-Chang Chiu: Miscellaneous Pharmacologic Actions of Citrinin. *J. Lab. Clin. M.* 946 317

Citrinin is the antibiotic substance produced by the molds, penicillium citrinum, aspergillus terreus, and aspergillus candidus. It is also found in a flowering plant, the crotalaria crispata. It is an organic acid but has not been synthesized. It is stable, and can be antiseptized at 15 pounds of pressure for 30 minutes without loss of antibiotic power. It has a fairly high antibiotic action on most gram positive bacteria but, unfortunately, it is rather toxic for higher animals. It has been reported as useful as though weaker than penicillin in the local treatment of sore throat of the common cold, and of abscesses. Nothing, however, has hitherto been reported about its local effects, possible injuriousness to the mucous membranes and skin, and its systemic effects and absorption from various regions especially after local applications.

Proposed concentrations of citrinin sodium in sprays, lotions and ointments for local application to the mucous membranes and the skin were not found to be demonstrably irritating or injurious, however the slight or moderate irritation which they produced was not objectionable as indicated by tests in animals and human beings. Concentrations higher than those proposed caused definite protoplasmic irritation or injury but this was temporary and readily reversible.

Systemic absorption of citrinin, in animals receiving high concentrations and doses by instillation into the nose or mouth is practically negligible. Blood concentrations of from 1:4,000 to 1:30,000 citrinin were demonstrable after the introduction of high doses of citrinin into the ligated esophagus and stomach and all portions of the intestine of rats and also after intramuscular injection.

Rapid intravenous injections of citrinin in doses of from 1 to 100 mgm. per kilogram caused immediate, though temporary depressor effects, which

increased with the dosage this was due presumably partly to direct cardiac depression, and partly to peripheral vasodilatation. The highest doses used could produce dangerous sustained depression. Slow intravenous injections of citrinin however had no such effect. A reversal of the depressor to pressor action occurred in atropinized animals.

The average bacteriostatic concentrations of citrinin in broth were 1:16,000 for the staphylococcus aureus, and 1:40,000 for the streptococcus hemolyticus. The antibacterial action was unaffected by human serum, increased by fresh human urine, and decreased by heated urine. Experimental staphylococcal infection in mice was not prevented with high doses (one-half the toxic) given intraperitoneally.

SAMUEL KAHN M.D.

Olsen, C. T.: The Use of Tantalum Oxide, Type 400, in the Treatment of Wounds. *Indust M* 1945 14 949.

This article is a preliminary report of the author's experience with the use of tantalum oxide type 400. During the war, tantalum for surgical purposes was in great demand in the form of sheet, foil and wire with probably its most successful surgical application in cranioleptasty. Of all the metallic implants it has the highest resistance to corrosion in vitro and in vivo. Furthermore body reactions to it are strictly minimal.

Discussion with metallurgists revealed that the healing properties of the tantalum metal must be due to the oxide coating of the tantalum which is always present. Therefore tantalum oxide powder was prepared in such a way that it was free of all fluorides and alkaline substances. As a dusting powder it is extremely soothing to areas of the skin which have been chafed or irritated. It is easily sterilized by heating at a temperature of 310 degrees F in a dry oven and repeated sterilizations do not affect it. It is a material which can be kept easily at hand and used in a perforated top glass bottle, a powder blower or sometimes by dumping it out of an open container and spreading with a sterile applicator.

Indications for use of tantalum oxide include avulsed finger nails, chemical burns, diaper rashes, weeping lesions. It can also be used for surgeon's gloves, for intravaginal application and as a packing for sockets of freshly extracted teeth.

The danger of secondary contamination due to redressing is practically eliminated by its use. Relief of pain is attributed to the tight sealing off which the tantalum oxide crust produces.

STEPHEN A. ZIEGLER M.D.

Burke, C. W., Bronstein, B., Hirschfeld, J. W., and Pilling, M. A.: In Vitro Action of Streptomycin on Bacteria. *J. Am. M. Ass.* 1946, 30 64.

Streptomycin has been shown to be effective against a variety of gram positive and gram negative bacteria both in vivo and in vitro. Before it can be used rationally in treating disease an evaluation of

dose intervals and sizes and determination of the bacterial susceptibility must be carried out. There are definite in vitro differences in bacterial sensitivity to streptomycin and within a given species strains may vary from extreme susceptibility to high resistance. The blood concentration of streptomycin reaches a peak soon after parenteral injection and then falls gradually to zero. To use the drug rationally one must determine if a high enough concentration is being maintained with reference to the sensitivity of the particular strain of bacteria isolated. Frequently a smaller dose or longer interval between doses may be sufficient to maintain a blood level more than ample to inhibit the in vitro growth of the invading organism. On the other hand these studies may indicate the need for larger doses given at more frequent intervals.

This study had a threefold purpose (1) to determine the sensitivities of several species of bacteria to streptomycin (2) to correlate these sensitivities with the serum concentration of streptomycin that may be maintained in patients and (3) to determine whether the bacteria investigated developed a resistance to streptomycin in vivo.

Bacteria were isolated from 38 patients with various infections such as peritonitis, empyema, septicemia, infected wounds and burns, urinary tract infections and pelvic abscesses. The urine or pus was cultured before and at intervals during treatment with streptomycin. Each organism present was isolated in pure culture but complete identification of all the bacteria was not made. The following organisms were identified: *Escherichia coli*, *Aerobacter aerogenes*, *Pseudomonas aeruginosa*, alpha and beta hemolytic streptococci and the staphylococcus. After the organisms were obtained in pure culture they were screened for their sensitivity to streptomycin following which their sensitivity over a narrower range was determined. The action of streptomycin on anaerobic organisms was not determined.

The authors describe their method of screening to determine the approximate sensitivity to streptomycin, and a method to determine sensitivity values within narrower ranges than those possible with the twofold serial dilution method.

It has been found that the parenteral administration of 500,000 S units of streptomycin will maintain a serum concentration of from 10 to 15 units until the end of 4 hours. Theoretically, then all bacteria reported in this article with a sensitivity of 8 units or less would be inhibited over a period of at least 4 hours by a parenteral injection of 500,000 S units of streptomycin.

Two hundred and twelve strains of bacteria were tested for susceptibility to streptomycin. The majority of the strains of *Escherichia coli*, *Proteus vulgaris*, *Aerobacter aerogenes*, staphylococcus, and streptococcus were susceptible in vitro to the blood concentration of streptomycin that can be maintained in the average patient over a 4 hour period when he has been given 500,000 S unit dosages of

from 5 to 8 S units per cubic centimeter of blood. The majority of strains of *Pseudomonas aeruginosa* investigated were found to be very resistant to streptomycin. Resistant strains of a given bacterium were isolated from patients subsequent to the isolation of sensitive strains. The assumption is that resistant strains developed from the sensitive strains. Diphtheroids were found to be either very sensitive or highly resistant to streptomycin.

ROBERT R. BIGELOW M.D.

ANESTHESIA

Wilson, C. H.: *Military Aspects of Early Analgesia and Anesthesia Current Res 1946, 5*

The instructional approach to the military aspects of early analgesia and anesthesia at the Medical Field Service School had to be basic enough to include all of the important phases of the subject, and at the same time show the well trained anesthetist the problems he would encounter in forward anesthesia. This article discusses the overall problems involving analgesia and anesthesia in the combat areas.

The basic factor which determined the analgesic or anesthetic agents used was their availability. The drugs available to relieve pain were eugenol, acetyl salicylic acid, codeine sulfate, morphine sulfate and morphine tartrate. The two narcotics available were phenobarbital and sodium amylal. The morphine syrette proved invaluable in the combat zone. One-half grain of morphine tartrate was dissolved in 1½ c.c. of fluid placed in a tube with a rubber diaphragm and needle and kept sterile with a celluloid shield. This simple morphine tube simplified injections in the combat area.

Morphine was contraindicated in head injuries, lung irritation from war gases, heat cramps, conditions resulting in anoxia and respiration depression and conditions in which the symptoms had to be observed to determine the necessity of operative intervention. Stress was laid upon the use of morphine to relieve pain.

The anesthesia used forward of the evacuation hospitals had to be simple, safe, portable, and rapid in action control. Procaine hydrochloride was the agent of choice for nerve block. Inhalation agents were limited to ether and chloroform was used as a reserve agent. The instructions concerning the use of intravenous anesthesia had two purposes. First, to keep medical officers informed and up-to-date concerning the official opinion of the Army Medical Department on the use of pentothal sodium. Second, to give basic facts about pentothal sodium to those physicians who had little or no knowledge of the drug. Care must be taken not to inject pentothal into an artery. The dangers of this drug were enumerated. It was considered hazardous in cases of morphine overdosage, shock, infection of the neck, cervical or sublingual infections, in operations with great blood loss and those involving the airways. The

methods of resuscitation were enumerated. The use of analeptic drugs was discouraged.

Spinal anesthesia had little value in the advanced medical units during active campaigning but was used in the clearing stations. Whenever available, inhalation anesthesia with positive pressure apparatus was preferred for serious chest injuries. General inhalation anesthesia was slow to give adequate relaxation for intra-abdominal surgery and pentothal sodium was used more frequently than any other anesthetic agent by both the British and Americans in the many forward installations.

MARY KAY M.D.

Beecher H. K.: *Pain in Men Wounded in Battle. Ann Surg 1946, 3: 96.*

Two hundred and twenty-five freshly wounded men in the combat zone were studied for this report.

Attempts were made to correlate the pain with the extensiveness of the wound and to question the routine employment of morphine in these wounded patients. Consecutive cases were observed with no selection other than that they had one of five kinds of wounds chosen as representative: extensive peripheral soft tissue injury, compound fracture of a long bone, a penetrated head, a penetrated chest, and a penetrated abdomen. The patients chosen were clear mentally and were not in shock at the time of questioning.

The findings were as follows: 32 per cent had no pain, 35.6 per cent had slight pain, 18.6 per cent had moderate pain, and 13.7 per cent had severe pain.

Patients with penetrated abdomens had by far the most pain, possibly because of the spilling of blood and intestinal contents into the peritoneal cavity. Of all the patients considered, only one-fourth, on direct questioning, stated that their pain was severe enough to require pain relief therapy.

Data were presented to show that morphine was often administered by rote and not according to the patient's needs. When morphine was necessary, the intravenous method was considered optimal to avoid the possibility of long delayed action during periods of peripheral circulation shock. Morphine should not be used in nervous or manic or hysterical states to allay fear or to promote sleep for these purposes. Small doses of barbiturates have been adequate. Morphine should not be given in shock, unless pain is present in hypothyroidism, in the presence of dysfunction of the liver or when even a mild degree of anoxia exists.

Delayed morphine poisoning has occurred in battle casualties when the peripheral circulation was sluggish or inactive as it might be in patients who are chilled and have low blood pressure.

The treatment of morphine poisoning includes the placing of a tourniquet, intermittently loosened proximal to the site of the injection, the prevention of anoxia by oxygen administration and artificial respiration, and the intravenous administration of atropine (gr 1/160) or ephedrine (gr 1/4) as a central stimulant. Hypertonic glucose may be

given intravenously to aid diuresis. Body heat should be conserved if necessary. Regional nerve block proper splinting and bandaging are of use in allaying pain. Wounded men need sedatives of the barbiturate type as well as barbitals at times and small doses of both types of agents will accomplish what large doses of either alone will fail to do.

The man in shock complains far less frequently of the wound pain than he does of the great distress caused by thirst.

Donatelli L.: Mephedine as a Pharmacologic Product for Preparing the Patient for Anesthesia (La medicina come farmaco de preparazione alla anestesia). *Polidin* (as *ca*) 1945 53: 103

Mephedine is a new synthetic alkaloid derived from piperidine (ethyl-ester of the hydrochloride of 1-carboxylic acid 4-methyl-4-phenyl-piperidine) was subjected to a series of studies by the author at the Institute of Pharmacology and Toxicology of the University of Florence and Toxicology of the University of Florence. These studies were calculated to determine its qualifications as a so-called preanesthetic preparation that is a preparation to render the induction of general anesthesia easier and less harmful to the patient. These studies might be divided into four groups or propositions in the first the action of mephedine on somatic and psychic sensitivity was investigated. In the second any synergistic effects between mephedine and general and local anesthetic agents were considered. In the third attempts were made to clarify any influence of mephedine on the more important and more common nervous reflex systems capable of suffering operative or anesthetic result with reflex injury to the more vital vegetative functions and finally in the fourth attention was directed to any injurious secondary actions provoked by mephedine.

Group 1. The technique for this study in determining depression of the somatic sensitivity was that of Hillner (*Dieck and Ilck* 1939 p 731) using guinea pigs and the degree of the drug effect was graded according to the degree of the drug effect was stimuli (pinching of the animals' response to painful stimuli) (pinching of the ear lobe). The subcutaneous injections of 1 per cent mephedine in a dosage of 15 mgm per kilogram were found to have little effect on the pain response whereas with dosages of from 20 to 50 mgm the analgesic action became progressively more intense with complete analgesia at the highest dosage. The effect became maximum within 10 minutes and lasted for from 60 to 120 minutes. Since Mancini has determined the minimal lethal dose for guinea pigs to be 150 mgm per kilogram the great margin of safety of mephedine deserves notice.

For measuring psychic depression (preoperative anxiety) of this drug mice (*mus musculus*) were used after being accustomed to finding their way to food through a specially constructed labyrinth. After several days of accustoming the animals they would be given subcutaneous injections of

from 25 to 50 mgm per kilogram of mephedine and the subsequent time for traversing the labyrinth was observed. Again it was found that 25 minutes after 25 mgm had been injected and more pronouncedly when 50 mgm were used the animal had lost completely his ability to traverse the labyrinth this effect disappeared more or less completely after 85 minutes. Some of the animals especially those given 50 mgm became permanently lost in the labyrinth.

Group 2. For the study of the potentiating effects of mephedine a general anesthetic preparation was selected and also a peripheral or local agent. The general anesthetic was the sodium salt of 5 (alpha-methyl-beta-cyclohexyl) 1-methyl barbituric acid (evipal) and the local anesthetic was procaine (procaine hydrochloride acid). A third (general) anesthetic prepared was ether. A third (general) olive oil for subcutaneous injection. This animal employed was the rat (*mus rattus*). This animal was considered completely narcotized when it had fallen on its side its head had fallen loosely the body was immobile and there was no reaction to painful stimuli.

In this experiment the animals were divided into groups: a control group receiving subcutaneously from 1 up to 10 c.c. of the ether (in 1 c.c. increases) in oil the test group receiving 50 mgm per kilogram of mephedine which by itself always left the animal normal or perhaps even a trifle excited—this was followed 30 minutes later by the amounts of ether in oil specified for the control group. It was found that the rats treated previously by mephedine fell under narcosis much sooner than the corresponding control and slept much longer and more deeply. For instance with the dosage of 7 c.c. per kilogram of ether in oil the control slept for 3 minutes while the animal receiving the preliminary treatment with mephedine slept deeply for 87 minutes. While 5 c.c. of ether in oil were not sufficient to bring the animal under narcosis but produced definite narcosis in pre-treated subjects. The potentiating effect of mephedine on the anesthetizing power of ether in oil is so great as to reduce to one half or even to one third the amount of ether necessary.

In the corresponding studies on mephedine and evipal the conditions were generally the same except that guinea pigs (*cavia colaya*) were the experimental animals used. Evipal in a 1 per cent solution was injected intraperitoneally in every animal subcutaneously from 25 to 50 mgm being used per kilogram of body weight of the guinea pig and the criteria of narcosis remaining the same for this animal as for the rat in the previous study.

With the larger of the 2 dosages of mephedine cited (50 mgm per kilogram) torpor and analgesia would be produced but never narcosis while with the smaller dosage (25 mgm per kilogram) the effect was rather an excitation of the animal. Likewise with the evipal alone a 1 minute narcosis was required to induce a narcosis of 34 minutes while 50 mgm lengthened the narcotic period to 70

minutes. With the mephedine preparation, however the narcosis appeared sooner lasted much longer and was much deeper with more complete muscular relaxation. In fact, if 30 mgm. per kilogram of mephedine were administered to the subject previously, the 25 mgm. of evipal, which produced narcosis lasting for an average of 34 minutes resulted in narcosis lasting 73 minutes or more than twice as long and with the aid of mephedine 15 mgm. of evipal became sufficient to induce the narcotic state.

In the succeeding studies with evipal used intravenously on rabbits the same potentiation on the part of mephedine was observable.

In order to test any potentiative effect of mephedine on the local anesthetic power of procaine hydrochloric acid the corneal reflex of the guinea pig was used. This was induced by touching the cornea at second intervals with the Frey brush, from 2 to 10 such stimuli usually being sufficient. Procaine solutions in dilutions of 0.5 to 10 per thousand were instilled into the conjunctival sac and retained in contact for 2 or 3 minutes, the anesthetic action beginning at strengths of 0.5 per thousand. Mephedine given subcutaneously in doses of from 20 to 30 mgm. per kilogram and synchronously with the instillations of procaine induced corneal anesthesia, frequently intense even with the smaller dose of mephedine (20 mgm. per kilogram) which of itself does not induce any evidence of such loss of sensitivity and with the noneffective strength of procaine (0.7 per thousand solution). Similar effects were observed in subsequent experiments with rabbits as experimental animals, and there is little doubt left as to the potentiating power of mephedine on procaine hydrochloric acid with regard to its local anesthetic properties.

Group 3. To investigate the danger of damage or even death to the patient from reflex effects on the heart, respiration, or vomiting reflex, the rabbit was chosen for the experimental animal. It was tracheotomized and chloroform vapor was insufflated backward from the cephalad stump of the trachea through the pharyngeal and nasal passages and the resulting responsive effects on the heart action and respiration were recorded by kymographic tracings. The same technique and tracings were produced after the endovenous perfusion of 1 mgm. per kilogram of a solution of mephedine in such a manner that the animals received 33 mgm. per kilogram of this drug when the reflex characteristics of these tracings, before the injection of mephedine, had entirely disappeared. Therefore taking the reflex irritation of chloroform vapors on the nasopharyngeal area as typical of all induction irritation reflexes of the other anesthetics and such reflexes as typical of all the reflexes incident to general anesthesia which are dangerous to the life of the anesthetized. It seems evident that mephedine administered in advance of the inhalation anesthesia, is capable of depressing or even annulling all of the dangers arising from irritation of the upper respiratory tract.

Mephedine likewise seems to obviate the dangerous respiratory and cardiac reflexes due to rough

handling or pulling on a nerve during the operation. For this study the exposed sciatic nerve of the rabbit was stimulated electrically it being found that all evidence of such reflexes began to decrease with the perfusion intravenously (within a space of 7 minutes) of 7 mgm. per kilogram of mephedine, and that all trace of such reflexes disappeared with higher dosages.

Likewise in the case of the vagus reflexes, mephedine showed itself capable of suppressing the arrest of respiration and of the sudden hypertension and cardiac disturbances incident to stimulation of the central stump of the severed vagus nerve.

Identical results were induced in the nerve of Cyon of the rabbit, stimulation of which normally leads to such a sudden and severe bradycardia and fall of blood pressure the necessary dose of mephedine in this instance was 14 mgm. per kilogram.

Although mephedine does not entirely abolish the carotid sinus reflex it does attenuate such reflex and thus promises to obviate such incidents as arise during operations on the neck and floor of the mouth. These incidents are not always suppressed either by such anesthetic agents as evipal or by deep general inhalation anesthesia.

The author also investigated the reflexes due to pulling or other mishandling of pedicles and other forms of attachments of the organs. As a typical reflex he chose for study that produced by traction on the mesogastrium and suspensory ligaments of the stomach. This was accomplished by laparotomy tying the animal (rabbit) and attaching a forceps to the stomach then closing the abdomen, so that the stomach could be subjected to traction from the outside. Again the tracings showed that the consequent respiratory and cardiovascular reflexes could be abolished by the perfusion of 60 mgm. per kilogram of mephedine into the marginal vein of the rabbit within an hour's time.

Before concluding this section of his studies, the author reports some studies on mice. They had nothing to do with the suppression of reflex responses by mephedine but were practically related to them. They concerned the primary or induction excitation of the animal as produced by other types of anesthetic agents, of which he chose evipal as being typical. Six mice were injected endoperitoneally with 1 per cent solution of evipal, up to dosages of 20, 40, 60, 80, 100 and 200 mgm. per kilogram. Of these dosages, all except that of 20 mgm. produced violent excitation in the injected animal there were also clonic convulsive attacks followed by depression and ataxia. Forty milligrams produced convulsions and ataxia, but not narcosis and the animals recovered after about 30 minutes. 60 mgm. or more caused narcosis and death in from 45 to 100 minutes. 20 mgm. had no effect whatever. Six other mice, 30 minutes previously had received subcutaneous injections of 5 mgm. per kilogram (1 per cent solution) of mephedine, in these, 20 mgm. per kilogram of evipal induced narcosis without excitation within 10 minutes, which lasted several minutes. 40 mgm. or more produced death in narcosis without excitation.

Group 4. Mephedine in therapeutic doses exerts scarcely any or no action on the respiratory and cardiovascular systems but in large amounts it constantly brings about a lowering of the blood pressure and a reduction of the amplitude of cardiac contractions and of the respiratory frequency. These effects are however found with endovenous administration, but not with subcutaneous injection nor with very slow endovenous perfusion even in large doses. For instance with an endovenous perfusion of 60 mgm. of mephedine per kilogram in a rabbit accomplished within a space of 60 minutes the accompanying tracing did not show any substantial modification of the respiration however 10 minutes after perfusion of a rabbit with 60 mgm of mephedine per kilogram and per hour the tracing (revealing also the cardiac function) showed a lowering of the arterial blood pressure of about 30 mm of Hg and a diminution of the amplitude and frequency of respiration without any evidence of disturbance of the heart action. This however, tended soon to return to normal, so that at the end of 60 minutes (during which period 60 mgm per kilogram has been administered) all of the functions appeared to be perfectly normal.

In conclusion the author desires to call attention to the fact that mephedine exerts a spasmolytic action on all smooth muscle (vascular bronchial, and intestinal) which effect deserves the attention of the surgeon.

JOHN W BRECKMAN M.D

Allen F M Crossman L W, and Lyons, L V :
Intravenous Procaine Analgesia. *Current Res Anesth* 1946 25 1

The purpose of this work was to use intravenous procaine in the widest possible variety of painful conditions, the fundamental basis being that the great majority of pains are associated with local inflammation or edema. Thus, procaine diffusing through specially permeable capillaries may produce analgesia of the nerves in those tissues without important effects elsewhere in the body.

At first the original method as suggested by Lundy was adopted, with a 0.1 per cent procaine solution in physiological saline solution. The results of Lundy, Gordon, and McLachlin, and Bigelow and Harrison were confirmed. Subjective disturbances of over doses were dizziness, blurred speech, or mental confusion. The literature suggested epinephrine as the antidote for respiratory symptoms of intoxication and intravenous barbiturate for intoxication in the form of convulsions but the authors saw few of these complications. In the group of obstetric cases in which procaine was infused intravenously, this method created an optimistic impression that it might prove to be the ideal obstetric anesthesia and the fulfillment of the quest for the prevention of pain during childbirth. A barbiturate was always administered as preliminary medication. Case reports were given in detail illustrating the use of intravenous procaine in such conditions as nucleus pulposus gangrene, bed sore, and angina.

The authors modified the Lundy technique by increasing the quantities of infused fluid and procaine by lengthening the period of infusion, by using glucose solution when saline solution might conduce to harmful edema, and by extending the range of application of the tests to all kinds of painful conditions. The method was found to have definite though limited value and when hypersensitivity to procaine had been excluded by preliminary tests and when the administration was kept within the limits set by dizziness or other subjective symptoms there appeared to be no danger whatsoever.

The experience with obstetric operations was extended to ordinary surgical operations of which a case records were summarized as examples of the method. In a hip pinning 375 c.c. of salt solution containing 2.75 gm of procaine were used during the course of 1 1/4 hours and 4.25 gm of procaine were used for a cholecystectomy in the course of 1 1/4 hours. The first patient remained practically unconscious throughout with wide open staring eyes and a wild expression, but later on questioning he claimed that he could remember what was said and done during the operation but that he had no pain at any time. The second patient had the appearance of normal sleep with a peaceful facial expression and imperfect muscular relaxation. The method has the advantage of rapid and flexible control, absence of accompanying injury or after effects and a high degree of safety as far as can be judged to date. As soon as possible, collaborative studies will be published which will attempt to establish a more adequate basis for acceptance or rejection of the method.

The infusion in higher dosage has produced a clinically new form of general anesthesia by action upon the central nervous system. It is hoped that this method will prove valuable for various purposes, but there has not yet been sufficient experience to define accurately the uses, limitations or possible dangers.

MARY KARP M.D

Lobachev S V : Refrigeration Anesthesia in Surgery of the Extremities. *Current Res Anesth* 1946 25 22

Investigational work was done at the Sklifosovskii Institute of Moscow on the technique of refrigeration anesthesia, the history and bacterial flora of cooled tissues, and the relation of this anesthesia to shock. The material consisted of 100 cases 87 of which were traumatic injuries 4 of gangrene due to vascular diseases and 9 of septicemia. Refrigeration anesthesia was considered excellent in 75 per cent of the cases good (slight pain on handling the nerve trunks) in 22 per cent, and poor (addition of ether required) in 3 per cent. Postoperative complications occurred in 12 cases 4 developed wound infections. The mortality rate was 3 per cent, 2 patients succumbing within 24 hours to a high stage traumatic amputation of both thighs complicated by brain injury and a third pa-

tient dying from milary tuberculosis of the lungs months after the operation.

The tourniquet site selected was encased in ice for from 15 to 30 minutes, and then the tourniquet was applied. Soft elastic rubber was used for this purpose the width of the rubber making no difference. The extremity was lifted prior to the application of the tourniquet in order to drain away the blood. The limb was then placed on a leather sheet filled with ice or snow and this was covered with another thick layer of ice or snow extending to from 5 to 10 cm. above the tourniquet. It was found that the temperature of the deep structures at the site of the incision was between plus 5 and plus 10 degrees C when the anesthesia was sufficient for surgical intervention. More intensive cooling caused irreparable damage to the tissues, while higher temperature resulted in unsatisfactory anesthesia. Without a tourniquet the cooling was unequally distributed. The cooling time needed was from 90 to 120 minutes for the thigh, from 60 to 90 minutes for the leg and from 45 to 60 minutes for the arm and the forearm.

The temperature of the stump gradually returned to normal an hour after the tourniquet was released. After the stump was dressed it was covered with ice packs for 48 hours and the sutures were removed 12 or 13 days postoperatively as the healing was somewhat retarded because of the reduced metabolism of the cooled tissues.

It was found that pain sensibility of the limb was the first to disappear on cooling followed by loss of temperature sensation, and finally by loss of tactile senses. Histologically the tissues examined during refrigeration did not differ from those of normal controlled tissues.

Primary suppuration was rarely found in spite of the injuries contracted in the streets. The bacteriological studies showed that the growth of microorganisms was inhibited. The pulse was not altered even in serious cases but respirations were accelerated. The temperature remained normal in that part of the body not refrigerated. There was no increase of palor sweat cyanosis during the operation. The patient usually responded to stimuli more actively as soon as refrigeration was effected. Apathy and somnolence gradually disappeared.

The advantages were summarized as follows

1. No anesthetic drugs are introduced into the system.
2. There is a local reduction of temperature which counteracts the traumatic shock by numbing the tissues and especially the nerves.
3. The application of the tourniquet and the cooling of the limb retards the formation and absorption of toxins.
4. Toxemia is reduced and shock is controlled.
5. This method has special advantages in the aged and in patients who are seriously ill with septicemia.

MARY KARP M.D.

which then appears to be embedded in a spongy mass. Myositis ossificans may add further layers of calcium around the joint. Numerous loose bodies are frequently present, often arranged in clusters to give the so-called "bag of nuts" appearance. Although considerable swelling is usually present, fever and other signs of inflammation are absent. The lesion may therefore, progress unattended until multiple fractures in the adjacent bones and a dislocation cause complete mechanical disability.

A complicating pyarthrosis may make the differential diagnosis difficult. Ordinary degenerative arthritis may be distinguished from neurogenic joint lesions by the absence of subchondral cyst formation in the latter. The rapid progression, the severity of the lesions and if present a perforating ulcer of the foot supplement the diagnosis of tabetic arthropathy.

A spontaneous fracture or a fracture after slight trauma may be the first sign of tabes.

GERHART S. SCHWARTZ, M.D.

Bauer, G.: Observations on the Technique of Phlebography. *Acta rad. et Stockh.*, 945, 26-377.

The author who has conducted 500 phlebographies since 1938 reports his findings in 180 leg phlebograms of patients suspected of developing thrombosis of the leg veins. The purpose of these examinations was to make possible the early therapeutic administration of heparin or dicumarol, which indeed succeeded in preventing the spread of thrombo-

phlebitis to the thigh in all treated cases. The findings were as follows:

In 73 cases the failure of the deep veins to visualize was considered evidence of thrombosis. In 62 cases there was good or fair visualization of all the main veins. None of these patients developed signs or symptoms of thrombosis subsequently. Eighteen cases displayed sectional occlusion of a vein with dilatation of the preceding vessel segment. In 27 cases single or multiple filling defects were found. In 42 of the 45 cases comprising the latter two groups, good circumstantial or indirect evidence of thrombosis could be established.

From his findings the author draws the following conclusions:

1. The most reliable x-ray sign of thrombosis is nonvisualization of the deep veins. An apparent constriction of a visualized vein to a threadlike caliber represents sedimentation of the contrast material and is not significant. It occurs only if the leg is placed in the horizontal position, a position which, nevertheless is to be preferred to the vertical for various other reasons.

2. Another valuable sign is filling defects caused by nonocclusive space occupying thrombi in the veins. These might be confused with false filling defects which are located at ramification points of the vessels. They are caused by displacement of the contrast material by reflux of the fresh blood from a side vein into the visualized vessel and are smaller than the former.

Various techniques are discussed. The author recommends perabrodil or diodrast (35 or 50%) for contrast material. An acceptable substitute is a mixture of equal parts of Intron and physiological saline solution. It necessitates, however the flushing of the veins with from 10 to 20 c.c. of saline solution in patients who experience cramplike pains in the calf after the injection. Section of the lateral malleolar vein is preferred to percutaneous venipuncture. Two stereoscopic films are better than a single film but not as good as a single frontal and a single lateral film of the leg combined.

Lodge, T.: The Anatomy of the Blood Vessels of the Human Lung as Applied to Chest Radiology. *Brit. J. Radiol.* 946, 9.

The literature on the gross anatomy of human pulmonary arteries, veins, and bronchi is summarized with special stress on the topographical relationships of these structures and the part played by radiological methods in establishing them. The author then recounts his own findings in pulmonary bronchovascular relationships in the normal, which he plans to use later as a base for radiographic study of pulmonary vascular changes in response to disease or physiological stresses.

In this present study of the normal three methods were used: the production of celloidin models by the modified corrosion technique (Fig.) radiography of the lungs following injection of the vessels with

Fig. 1. Celloidin model of the bronchi and arteries of the two lungs as seen from the posterior aspect. The trachea and bronchi are lighter colored and the arterial system is dark. Key to figure: A, trachea; B, apical artery; C, pulmonary artery; D, left pulmonary artery; E, axillary artery; F, pectoral artery; G, axillary basal artery; H, lingular artery; I, right main bronchus; K, right pulmonary artery; J, left main bronchus; M, pectoral artery; N, apical artery; O, axillary artery; P, first posterior horizontal; Q, second posterior horizontal; R, axillary basal artery; S, posterior basal artery.

Fig. 2. Chest roentgenograph showing particularly clearly the distribution of the main arterial trunks in both lungs. The right lower lobe vein can be seen between the tenth and eleventh ribs, and in the left midaxone the long tapering trunk passing downward is the lingular artery. The roentgenograph also illustrates thinning of the vessels at the left base, where there is clinical evidence of emphysema. These vessels should be compared with those of the right base, which are much thicker.

barrum sulfate suspension and tomography in the living subject. The author then applied the kinwledge so gained in ascertaining which anatomical vessels could ordinarily be seen and with what frequency and variation, in the posteroanterior roentgenographs of 200 normal individuals.

He stresses the generally accepted facts that the linear shadows seen traversing the lung fields in normal roentgenographs are produced by blood filled arteries and veins and not by bronchi, and that the vascular distribution of the left lung is essentially homologous with that of the right, the lingular artery on the left substituting with considerable exactitude for the right middle lobe artery with the exception that the former is derived from the left upper lobe artery and the latter from the right intermediate artery.

In general, the author's findings in vessel bronchus relationships in the human being were similar to those of Miller in the lungs of pigs and dogs and followed Greineder's law namely that artery bronchus, and vein are found in that order proceed

ing anticlockwise in the right lung and in the same order but clockwise in the left. The whole pulmonary arterial system was seen to follow the branching and whereas the veins tended to lie distant from the bronchi in their interspaces and to cross the bronchi at an angle.

Some veins may be seen to cross the arteries at an angle of almost 90 degrees an observation useful in differentiating veins from arteries in the roentgenograph.

On attempting to apply the knowledge gained by these studies to the survey of the roentgenographs of 100 normal subjects the author found it possible to recognize and name the majority of the first and second order branches (Fig. 2). He calls attention to the fact that the shadows of the veins are in general, less dense and less clear cut, but wider than those of the corresponding arteries and to the observation that vessel shadows are either straight or gently curved but never tortuous or taut.

LILLIAN DONALDSON M.D.

Plahler G. E.: The Development of Roentgen Therapy during 50 Years. *Radiology*. 945, 45 505.

The author remarks on the almost immediate attempt on the part of physicians in all parts of the world to turn Roentgen's discovery of the x rays in December 1895 to therapeutic uses. The interest in fluoroscopic examinations with the new rays in the absence of any protection or any warning sensations early led to recognized damage of the skin of the hands and faces of the investigators while in some patients the prolonged exposure time necessary for making skull plates resulted in alopecia. The discovery of this epiling effect led Freund to treat a disfiguring hairy nevus in a young girl. He reported his results in January, 1897, and widespread use of x rays in the therapy of skin diseases followed.

At the time of the discovery of x-rays the essential equipment—Ruhmkorff or Tesla coils or a static machine and Crookes tubes—was already at hand in every well established laboratory of physics (Figs. 1 and 2) and hence the necessary parts were quickly available to physicians but dosage for a given procedure was unknown and there were no instruments to record the physical factors used. The intensity of the current and the penetrating quality of the rays were estimated by holding the hand in front of the fluoroscope dosage was estimated by biological effect—erythema or epilation. Ammeter milliamperemeter and spinthrometer were however, developed relatively soon and the intensity of radiation and dosage began to be estimated by photographic effect or the darkening of barium platinocyanide dices. The small volume of current produced in early apparatus necessitated tremendous exposure times, so that the tubes quickly became overheated and the rays softer. The development of the interrupterless coil by Snook in 1905 leading to great increase in volume of the current produced the modifications of the Crookes (gas) tube together with accessory radiator and

Fig. 2. a. Crookes tube, reproduced by H. C. Remickler. Westinghouse Electric & Manufacturing Co. from designs furnished by M. Ischeller to represent the type of tube used by Roentgen in his discovery of the rays. Observe that the target was the bottom of the glass tube. b. One of the tubes used in the Medical-Chirurgical College laboratory by M. K. Kamahian. This tube, made in 1897, has a cup-shaped cathode and an iridium-platinum target. The size of these tubes is indicated by the tape measure (in inches). It will be observed that the bulb of the tube shown in B is not more than 3 inches in diameter.

water cooling devices, and finally the development of the hot cathode high vacuum tube by Coolidge in 1913 overcame many of these early difficulties. These advances made possible sufficient constancy in volume and quality of the rays to enable radiologists to duplicate diagnostic and therapeutic results in different patients. It was years however before the ionization effects produced by the x-rays first reported by Roentgen in March 1896, led to the development of practical instruments for their measurement and the establishment of the unit of dose the roentgen in terms of that ionization (1928).

Early therapeutic radiation was unfiltered. For the depth dose measurements in 1904 showing that the intensity of the x rays diminishes rapidly from the surface to the depth of the body treated and that this decrease in intensity is much less if an absorbing layer such as 1 mm. of aluminum is placed on the surface led to the use of filters in Europe. When higher voltage equipment became available with the production of a greater proportion of shorter rays filtration was increased both as to thickness and density of the metal chosen.

As it became possible to produce x-rays of varying qualities knowledge of the type of ray best suited to

Fig. 1. The first shadowgraph, made accidentally by Prof. A. W. Goodspeed of the University of Pennsylvania while working with the rays from Crookes tubes in February 1896.

the condition to be treated had to be sought and the technique of application worked out. It became generally accepted for example, that in the treatment of ringworm of the scalp the epilation dose should be given accurately at a single sitting even though a large area is covered but in most inflammations and malignant neoplasms the full dose should be divided that for acute inflammations the dosage should be very small and given at short intervals and for chronic inflammations larger doses and longer intervals are indicated. Bergonie and Tribondeau had found in 1903 that immature cells and cells in an active stage of division were more sensitive than those which had already acquired the stressed or resting stage and 10 years later Regaud stressed the importance in the treatment of malignancies of fractional doses of comparatively low intensity extending over a long period since more neoplastic cells would thereby be exposed to irradiation during phases of mitosis. Coutard used these principles when, about 1920 he modified the treatment of malignant tumors especially of the oropharynx and larynx to obtain a high total dose with increased destructive effect on the tumor cells but with relatively less damage to the overlying normal tissue than had been possible with some of the previous methods. Recent development of supervoltage equipment has presented further problems in dosage.

Foulcra, B. R.: Investigation Into the Time Factor in the Roentgen Irradiation of Cancer Cells. *Acta rad. Stockholm*, 1945 26 463

A round cell sarcoma and a certain type of mouse carcinoma were irradiated by x rays of varying intensities over varied periods of time and the result was compared.

The tumor tissue was transplanted to a homologous strain of mice before irradiation. All of the mice then received irradiation of the whole body. After a period of not more than 24 hours after completion of the exposure (depending on the experimental group) the tumors were removed from the mice. The tumor tissues of all mice of the same experimental group were then mixed by mincing in order to minimize the individual variations. This tissue mixture was transplanted into a number of healthy mice and the effect of irradiation was then assessed.

(1) By the take percentage i.e. the percentage of animals in which the tumor grew after transplantation and irradiation.

(2) By the mean latent period i.e. the number of days after which 50 per cent of the takes became apparent as palpable tumors. (The normal values for nonirradiated tumor tissue are 5 days for sarcoma and 6 or 7 days for carcinoma.)

Four intensities of radiation were used 58 r/min, 33 r/min, 3.3 r/min and 1 r/min. The delivered dose was the same in all of the cases i.e. 1,600 r to mice with sarcoma and 1,600 r to the mice with carcinoma. A middle dose was delivered by a single

exposure of the mice to continuous radiation of constant intensity which varied only with the experiment. This necessitated exposure times ranging from 20 to 1,600 minutes.

The principal findings were as follows:
1. Round cell sarcoma. The take percentage dropped 25 per cent and the mean latent period rose from 15 to 18 days when the intensity was lowered from 58 r/min to 1 r/min. The main change was observed at the lowest intensity which is therefore considered a critical intensity. This tumor is thus more sensitive to low intensity radiation. The most effective intensity has not been reached in the experiment but can be assumed to lie below the critical intensity of 1 r/min.

2. Krebs No. 2 mouse carcinoma. A drop of the intensity causes a proportionate rise of the percentage takes (up to 20%) and a reduction of the mean latent period from 17 to 13 days. This indicates that protraction reduces the effectiveness of radiation on this type of tumor. No critical intensity was observed with this tumor.

A number of histological examinations of both tumors was performed after exposure to staggered doses of x rays (in steps of 500 r) in order to study the relation of the cell life cycle to radiosensitivity. Within the studied range only the sarcoma displayed a cyclic response, to irradiation. Mitosis of the sarcoma cells was increased after a certain low dose of x rays was delivered to the specimen.

The author arrives at the following conclusions:
Within the studied range the carcinoma becomes more radioresistant with increasing protraction, probably because the cumulative effect of radiation is more than counteracted by the recovery which takes place during the low intensity irradiation.

The sarcoma becomes more sensitive to radiation with increasing protraction because of the increased probability that the cells are affected during the sensitive phase of their cycle. This cycle may be intrinsic (the sensitive phase being the stage of premittosis) or induced by the physicochemical action of the x rays.

Timmes, J. J.: Radiation Sickness in Nagasaki. Preliminary Report. *U.S. War Med. Bull.* 1946 46 219

The author in this preliminary report presents his observations made in Nagasaki on the radiation effects resulting from the explosion of the atomic bomb. The study was begun 33 days after the initial blast. It was conducted at an improvised hospital established at the Chinkoen Primary School a fact which explains the many difficulties encountered.

In the beginning an average of 20 new cases were admitted to the hospital daily but within 2 weeks this number dropped to 1 or 2 new cases daily. The

Investigation was abruptly terminated on September 25, 1945 but some follow-up reports were secured later and they were sent to S. L. Warren and Shields Warren in charge of the Army and Navy scientific atomic bomb commissions, respectively.

The explosion of the atomic bomb is associated with a sudden excessive release of pressure, heat, and radiation. The effects of the pressure and heat on human beings differ in no way from those of the ordinary bomb but the release of radiant energy is something new.

The first concern was the possible remaining radioactivity on the ground and in the victims. The bomb was exploded at an estimated altitude of 800 feet with the aim to expend as much as possible of the radiant energy into the atmosphere. The author buried x-ray films in the bombed area, attached others to various objects about the so-called crater (a true crater does not exist). They all remained negative. Later investigators with the aid of the Geiger counter, likewise found the area safe as this extremely sensitive instrument registers only negligible amounts of radiation. The effect on the victims was studied by attaching x-ray films to their limbs for 18 hours. These too remained negative.

Another point of interest was the radiation sickness. The Japanese claimed that most of the deaths occurring during the first week after the blast were the result of this illness. However, they did not differentiate between blast victims and radiation victims and attributed many of the thermal burns to radiation burns. It is the author's impression that a large percentage of the early victims indeed died of the radiation effect. This is explained by the fact that most of the civilians were not in air raid shelters when the bomb was dropped. Concrete walls of 2 feet thickness probably would have afforded adequate protection.

A study of the patients themselves reveals some interesting data. All victims observed had been within 3 kilometers of the center of explosion.

There were only a few x-ray skin burns and they were mild in character. However, many cases of alopecia were seen. In some the hair started to fall out 1 to 3 days after the explosion, in others about the third week. At the end of a month a few of the patients had already begun to grow new hair of a downy nature. In none of the cases was the loss of hair complete.

The most important effect of the radiation was on the bone marrow. The majority of the cases exhibited an aplastic type of anemia. A white blood cell count under 1,000 indicated a poor prognosis although 1 patient with a 400 count recovered. In some instances the blood cells completely disappeared before death. Petechiae, gross hemorrhages, increased bleeding times (often above 45 minutes), thrombocytopenia, and urine revealing the presence of nephritis were noted frequently.

The average newly admitted patient complained of fever, malaise, loss of appetite, bleeding gingivae and hemorrhagic diarrhea. Oral changes constituted common occurrences. The tongue was of a smooth glossy appearance and the mucosal membranes showed changes varying from a simple inflammatory lesion to deep necrosis. The teeth were generally loose and easily removed by hand. Two cases of necrosis of the mandible and 1 of the maxilla were seen. Terminal infection, particularly bronchopneumonia, was found to be the most frequent immediate cause of death.

The prognosis was difficult to evaluate. Youth and a progressive rise in the white blood cell count represented good signs.

Therapeutic opportunities were limited.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Emerson, C. P., Jr. and Ebert R. V.: A Study of Shock in Battle Casualties. *Ann Surg* 1945 122 745

One hundred and twelve battle casualties admitted to a field hospital with serious abdominal chest, or extremity wounds have been studied by the authors. Fifty per cent of these patients were in severe shock. Detailed clinical observations were made in all cases as well as serial determinations of either the hemoglobin concentration or hematocrit reading. Measurements of the plasma volume and plasma protein concentration as well as hematocrit readings were completed in 57 cases in 33 cases multiple blood volume determinations were made either in the course of transfusion therapy or before and after operation.

The arterial blood pressure was found to provide the most reliable clinical index of blood volume deficiency. All patients with initial systolic pressures below 85 mm. of mercury excluding those with spinal cord transection were found to have marked oligemia, the deficit averaging 40 per cent of the expected normal blood volume all patients with this degree of hypotension had a diminution in blood volume that exceeded 25 per cent.

Blood volume and plasma protein measurements indicated that some degree of spontaneous hemodilution with low protein fluid often occurred in patients suffering from oligemic shock the amount of this dilution, however, was small rarely exceeding 300 c.c. It is concluded that a normal hematocrit reading or the demonstration of a mild anemia with a few hours after injury is no indication that a severe blood loss has not occurred. Severe anemia was produced by the administration of plasma to patients with marked oligemia.

The majority of patients presented no evidence of an excessive loss of plasma in proportion to the red cells in a few with severe abdominal wounds there was demonstrated a disproportionate plasma loss which resulted in a mild degree of erythroconcentration. The average total blood loss estimated to have occurred in cases of severe shock before admission to the hospital was 63 per cent. Hemorrhage appeared to have been most severe in patients with wounds of the extremities and least severe in patients with uncomplicated chest wounds.

Blood volume measurements were performed preoperatively and postoperatively in 10 cases in order to ascertain the degree of blood loss occurring in the course of various surgical procedures. The average loss in 3 patients subjected to open thoracotomy was 600 c.c. 5 patients requiring extensive abdominal surgery had an average of approximately 2 200 c.c.

Serial determinations of the blood volume indicated that hemorrhage occurred during the course of transfusion therapy in 11 of 23 patients studied. This complication was encountered most commonly in patients with severe wounds of the extremities, a majority of these patients suffering a loss which averaged 40 per cent of the blood and plasma transfused.

Plasma protein measurements before and after the injection of blood diluted with equal volumes of preservative solution indicate that retention of the latter in the blood stream is transient and not enough to produce significant hemodilution.

The mortality incidence of all patients admitted in severe shock was 32 per cent. of those whose arterial pressure on admission exceeded 85 mm. of mercury 11 per cent died within a similar period which included the first postoperative day. The majority of deaths were due to penetrating abdominal wounds. Cases are described in which the clinical signs of shock were unrelieved by therapy despite complete restoration of the blood volume to normal. The factors operative in the production of irreversible shock included severe infection lesions in due to pulmonary damage and long persisting combinations of anemia oligemia and hypotension with terminal signs of myocardial insufficiency.

Therapeutic indications for the use of whole blood and plasma are cited, and criteria for evaluating the requisite amount of transfusion therapy are discussed.

JOSEPH GASTER, M.D.

Brun, C. Knudsen, E. O. E., and Rasmussen F.: Post-syncopal Oliguria. Kidney Function and Circulatory Collapse. The Cause of Post-syncopal Oliguria. *Acta med scand* 1945 122 381 486

In the passive erect posture with a tilting board unintentional circulatory collapse occurs frequently. This is immediately followed by reduced diuresis which the authors call post-syncopal oliguria. This article deals with the investigation of renal function during post-syncopal oliguria and the cause of the latter.

Sixteen tilting experiments were done all of which were complicated by circulatory collapse. The oliguria lasted from 15 to about 90 minutes after the syncope the duration apparently being proportional to the fall in blood pressure. The diuresis always dropped to values of from 3 to 1 ml/min. and the specific gravity of the urine rose to about 1.030 or 1.035. The inulin concentration index during oliguria rose to about 120 from the normal of about 12 and the inulin clearance (glomerular filtration) was reduced slightly or excessively. In the latter instance when diuresis was resumed there followed briefly an increase to unexpectedly high values. The urea clearance was reduced in the period

Immediately after syncope and then followed by normal values. Fluctuations occurred as in the case of inulin and diodrast clearances but they were not nearly so pronounced presumably as a result of the increased return of urea in the tubuli during the oliguria.

Since plasma is cleansed completely or nearly so of diodrast by a single passage through the kidneys diodrast clearance was taken as a measure of the quantity of the renal plasma flow. Diodrast is excreted mainly in the renal tubules and only to a smaller extent by filtration in the glomeruli.

Diodrast clearance often was reduced slightly just after syncope and then returned to the initial value. However if the drop was great, there followed a marked temporary rise before the fall to normal. The filtration fraction was without significant change during the period of oliguria. Hemocoagulation occurred during syncope but after the individual had been put back to the horizontal posture there was a gradual dilution of the blood to a temporary lower than normal level toward the termination of the study. The blood pressure and pulse rate remained unaffected.

In the discussion emphasis is placed on the chance for error (savage phenomenon) in the clearance determinations which were then corrected and properly evaluated. Thus, the glomerular filtration and renal plasma flow are found to be normal during the period of oliguria.

These findings, together with the high concentration index for inulin and the high specific gravity for urine point to a greatly increased reabsorption of water in the renal tubules rather than to a decreased glomerular filtration as the mechanism which governs oliguria.

The authors then postulate that postsyncope oliguria is induced by a suddenly increased supply of antidiuretic hormone from the posterior lobe of the pituitary gland, reflexly stimulated by either the cerebral anoxia or by the effect on the pressoreceptors which is caused by the fall of the blood pressure.

Having postulated previously that an antidiuretic hormone from the posterior lobe of the pituitary gland was responsible for the greatly increased reabsorption of water in the renal tubuli which produced a postsyncope oliguria the authors endeavored to demonstrate the occurrence of this hormone.

First they tried to show that the effect on the diuresis is of a humoral nature by transfusing blood from newly collapsed subject. Three of the recipients sustained a diuresis fall comparable in severity and duration to the amount of blood transfused. In a out of 5 control experiment there was no change. The other recipient experienced a diuresis fall which was thought to be due to reflex action on the pituitary gland from repeated painful punctures during the venesection.

Since the posterior lobe hormone of the pituitary gland is proved to regulate the secretion of chloride in the kidney the chloride output in the urine was determined after collapse and after oliguria trans-

mitted by transfusion. The findings were identical with those observed after the ingestion of inulin, an antidiuretic extract of the posterior pituitary lobe. The minute chloride output did not increase but the chloride concentration index fell below 1 while the plasma concentration decreased and the chloride in the urine increased markedly.

Finally, studies were made on 2 patients suffering from diabetes insipidus. These patients are assumed to have a reduced production of antidiuretic hormone. The postsyncope oliguria was a marked one in normal people but of much shorter duration. The urine chloride concentration rose to considerably below the plasma chloride concentration. The same conditions prevailed after an inosipidin injection. The short period of oliguria would tend to point to an inability on the part of a patient with diabetes insipidus to produce antidiuretic pituitary hormone.

These three series of studies taken together suggest that postsyncope oliguria is conditioned by the pituitary gland. The authors are quick to point out that this type of oliguria is probably merely an accompanying phenomenon to another pituitary regulation, first and foremost being a regulation of the tone of the capillaries. The oliguria often seen clinically in circulatory insufficiency viz., in shock states from burns, anesthesia, and hemorrhage is designated as collapse oliguria in contrast to postsyncope oliguria, during which period the blood pressure is normal.

DANIEL H. LYNN, M.D.

Imperati L.: Malaria in the Practice of Surgery.

The Inter Relationships between Malarial Infections and Surgical Diseases (La malaria in chirurgia. Rapporti fra infezione malarica e malattie chirurgiche) *Gior Ital chir* 1915, 11:15.

The author was a captain in the medical branch of the Italian military forces in Sardinia stationed at first at the principal military hospital at Cagliari and later transferred to Iglesias. During this time he witnessed the disquieting recrudescence of malaria in that country and gained the experience which he details in part in a series of articles of which the first is covered by this abstract. A second article will be concerned with the problem of surgery in the patient with malarial splenomegaly, and a third will treat of surgery in the malarial patient.

After a relatively brief discussion of his subject—including the pathogenicity of the plasmodium at different places and times, and in relation to the varying resistance of the patient, the effect of chronic malaria on the reticuloendothelial system and the melanocytocytic foci of Henry—the author turns to the details of his own personal views and experiences. This discussion is again divided into subsections: the first concerning the malarial recurrences appearing as a result of surgical injuries and the second concerning the surgical syndromes occurring as manifestations of malarial infection.

In deciding on the complicity of the malarial plasmodium in the febrile condition of the patient

the author and his coworkers have depended as often on the leucopenia with the relative mononucleosis of malaria as on the actual finding of the parasite in the blood cells and malaria has been suspected even in continuous fevers since recurrent malaria is capable of producing a remittent continuous temperature. The author remembers one instance of a thoracotomized pleural empyema in which after a short favorable course a fever of a remittent continuous type suddenly developed. Intense and prolonged treatment with quinine produced a fall in the temperature, although no blood parasites were ever found.

The second part of this article discusses the cases in which the malaria itself produced surgical syndromes resembling those of appendicitis, cholecystitis or gastric or duodenal ulcer. Certain elements of the true surgical picture (vomiting, constipation, facies peritoneal and/or defense musculaire) were usually missing entirely and most of the other cases would not have deceived a physician experienced in the vagaries of malaria. However the author cites some dozen cases pronounced cholecystitis (3 cases) or appendicitis by the medical department and referred to surgery in all of which but 2 the malarial nature of the dolor abdominalis was recognized satisfactorily and in time. Perhaps the case history disclosed malarial antecedence or perhaps the abdominal wall was not sufficiently spastic for a defense musculaire and out of proportion to a seeming amount of pain present in any event quinine satisfactorily cured all but 2 of these cases only in 2 instances was laboratory help indispensable. The first instance was that of an artilleryman, who had been in Sardinia for 3 years. This patient had sudden violent attacks of abdominal pain, localizing to the right iliac fossa, which were accompanied by retention of feces and partially of gas, and some display of a neurotic disposition (weeping). Physical examination the following day disclosed facies aniosa, a temperature of 39 C, rhythmic, thrready pulse of 120 and a dry tongue; the abdomen was uniformly spastic, retracted almost still (borborygmi) and presented diffuse cutaneous hyperaesthesia. However the abdominal spasm was not a true defense musculaire as it was more or less equal in intensity on the two sides and could be largely influenced by distracting the patient's attention also. In addition, the patient did not look sick enough for the presence of a phlogistic process. Blood examination disclosed the plasmodium praecox in great quantity. Quinine did not control the fever until the second day and even then the other symptoms persisted some abdominal pain remaining for many days.

The second patient was an aviator, first class, who after 3 years in Sardinia suddenly developed intra costal pain, irradiating posteriorly and fever of 39.5 C. Quinine injections on this same day were unsuccessful and the patient was referred to surgery

under the diagnosis of acute cholecystitis. However the impression was rather that of an atopic, subhepatic appendicitis and the author was invited to examine the patient. The abdomen was found to be tensely spastic throughout and painful to palpation; the temperature was 39 C with some morning remission; the tongue was dry in the gall bladder region; the pain was more intense and there was some muscular defense at this point; neither the liver nor spleen was palpable. The topography and season suggested malaria, even though no parasites were determinable at blood examination; however there were only 4,000 white cells with 10 per cent monocytes and a few hemohistoblastocytes. Quinine therapy was again instituted and after 3 days the fever and pains had entirely disappeared. Here again the relatively good general condition of the patient throughout argued against a septic inflammatory process.

The author seems not to have encountered the phlogistic, even necrotic, processes at times ascribed by other authors to malaria itself such as the strumitis suppuratis of malarial origin of Ceballos and Gomez; malarial peritonitis Demjanow's appendicitis of malaria, Caruso's appendicitis of necrotic and gangrenous type, or the perivisceritis parasitaria of Peperio and of Donati and he leaves open the question as to their authentically malarial character. However he does cite an instance of hemoptysis in which operation did not reveal the origin of the bleedings and which he therefore ascribed etiologyally to the malarial parasite. He passed over such causes as (tumor) small vascular thrombosis, and the production of punctate hemorrhages capable of producing fatty degeneration to the theory of so-called neurotrophism of the malarial virus wherein degenerative processes in the vegetative system give rise to vasomotor disturbances, a true angioneurosis. This theory was strengthened by the author's observation of a malarial (plasmodium praecox) asphyxia and parasthesia pallida bilateralis of the feet which cleared up on a regimen of quinine antispasmodics (atropin) and hot applications.

Among the involvements of the nervous system have also been those resembling an ascending polyneuritis even involvements of the cord such as monoplegias with loss of reflexes and amyotrophias of the author's patients, apparently as a sequela of malaria developed a rather persistent neuritis of the radial nerve with medicolegal implications. The observation of the author which seems to be unique in the literature, is that of a tertian malaria with concomitant tumescence of the testicle and epididymis without involvement of the endovaginal serosa or cord. The swelling and pain which was present disappeared gradually following cessation of the febrile attack, the detumescence being too rapid and complete for a pyogenic or other phlogistic process, and seemed due solely to the malarial infestation. In conclusion, however, the author warns against a too ready acceptance of what might be a surgical condition in a malarial patient as an exclusive malarial

rial condition and he cites 2 instances: one a ruptured appendix and the other an intestinal perforation in a patient with typhoid fever in which operative therapy was deferred because of prejudice toward a malarial etiology of the abdominal pains. The patient with the ruptured appendix recovered later following operation while the patient with typhoid fever did not. **JOHN W. BUDDECK M.D.**

Waalder E.: A Chromaffin Tumor Simulating Graves Disease. *Acta med sc d* 1945 23 1

Tumors arising from chromaffin tissue are very rare. About 100 cases have been described in the literature. Eighty of them had their source in the suprarenal glands, while the remainder arose from the paraganglia. Eighteen cases of extrasuprarenal chromaffin tumors have been reported in the literature. In several cases the tumors have given rise to characteristic clinical manifestations the patients being subject to attacks of headache a sense of pressure in the epigastrium palpitation of the heart excessive sweating coldness and pallor of the limbs and a high blood pressure. In the intervals between attacks the blood pressure would be normal and the patient would feel well. Belt and Powell have given this group of symptoms the title of the suprarenal sympathetic syndrome. The true nature of the disease has often been overlooked in these cases.

In account of a misinterpreted case with pheochromocytoma originating in the right celiac ganglion is presented. A man age 49 had been well until 3½ years ago when he developed a disease characterized by palpitation of the heart, excessive sweating and nervousness which required hospital care on several occasions. During his first hospital stay the basal metabolism was 145 per cent (pulse 8) and the blood pressure 176/112 there was enlargement of the heart, and albumin in the urine and the latter contained erythrocytes and hyaline and granular casts. During his stay in the hospital the blood pressure was 190/125 185/112 170/130 and 116/114 and the basal metabolism ranged from 156 to 120 per cent. A diagnosis of Graves disease and nephritis was made and following preoperative therapy a thyroidectomy was done. The surgeon was in doubt as to the diagnosis at the time of the operation and his histological examination of the excised gland showed no changes characteristic of Graves disease.

The attacks of palpitation of the heart and excessive sweating returned. During the second stay in

the hospital the blood pressure varied between 230/140 and 155/90 but no relationship between it and the patient's symptoms was noted. The basal metabolism on four occasions was 140, 130, 116 and 108 per cent. The diagnosis was still considered thyrotoxicosis with hypertension.

Upon his third stay he became worse and death occurred with signs of a subarachnoid hemorrhage. Postmortem examination revealed the pheochromocytoma in the right celiac ganglion, a brain hemorrhage arteriosclerosis and arteriolar sclerosis, and enlargement of the heart. Analysis showed that the tumor contained less adrenalin than the tumors in several other cases investigated by the much more exact biological examination.

It is of special interest in this case that it was interpreted as one of Graves disease. The diagnostic mistake is of interest for two reasons. In the first place Graves disease was suspected in some of the cases of chromaffin tumor published earlier. Furthermore Belt and Powell drew attention in 1934 to the similarity of the syndrome of certain cases recently described as "nonglitterous hyperthyroidism" to the suprarenal sympathetic syndrome. In the second place it is interesting that the basal metabolism was increased in this case not only because such an increase was misleading to the diagnosis, but also because it provided matter for thought concerning the cause for such an increase. According to Cohen in 1937 adrenalin increases the metabolism by stimulating the action of the sympathetic system. It has been found that patients with chromaffin tumors are sympathicotonic, and it is natural to assume that in these cases an increase of the basal metabolism depends on an increased production of adrenalin. Hitherto the manifestations observed of chromaffin tumors have included a rise of the blood pressure, tachycardia, excessive sweating coldness of the limbs glycosuria, and hyperglycemia. To these manifestations one may add an increase of the basal metabolism which will also be found. **JOHN E. KARANT M.D.**

Alcohol, Bactericidal effect of mixtures of ethyl and water 69

Alcoholics, Serum amylase findings in chronic, with acute severe abdominal symptoms, 77

Allergy, Treatment of bronchiectasis with chemotherapy and management of 193

Allotax Glucose tolerance in rats following repeated small doses of 350

Ameba, Colitis due to, with special reference to perforation study of 80 autopsied cases, 294 abscess of liver due to, opening into peritoneal cavity 303

Amebiasis, Clinical significance of deformity of cecum in 396 roentgen findings in, of liver, 436

Amenorrhea, Renal hypoplasia with hydroureter and primary 222 use of prostigmine in treatment of and pregnancy test, 395

Amputation Major stump following, in health and disease, 245 nearlithosis of humerus shaft for at elbow 326

Amylase, Findings of serum, in chronic alcoholic patients with acute severe abdominal symptoms, 77

Anaesthesia, Intravenous procaine, 525

Anemia, Transfusion and heart, 60 aplastic, terminated by removal of mediastinal tumor 196 of newborn, 410 burns, collective review 443

Anesthesia, Use of curare in sodium pentothal nitrous oxide oxygen, 70 prolonged, 71; 5 years' experience with caudal in private obstetric practice, 71, meningitis after spinal analgesia, 71; pentothal sodium use in continuous intravenous, and method of preserving in solution, 72 by combined intravenous pentothal sodium and local nerve block, 73; factors influencing trends in 162 hazard of amnesia during nitrous oxide, 162 influence of liver and kidney on duration of produced by barbiturates, 162 roentgenological study of male sacrum as aid in caudal analgesia, 163 continuous caudal analgesia in curettage for abortion, 163 efficiency of "penethal" (2-methyl-amino-heptane) as vasopressor substance for spinal, 163 for men wounded in battle, 243 sulphydryl protection of liver 263 effect of local on cell division and migration following thermal burns of cornea, 266 in ligation of patent ductus arteriosus, 282 utility of apomorphine in clinical, 349; in maxillofacial surgical unit with British liberation army, 341 present status of ethylene oxygen 342 pericardial spinal, combined with evipal narcosis, 342; with nerve paralysis after spinal analgesia, 343 effects of adrenalin and nembatal on blood constituents before and after splenectomy 402 spinal analgesia in operative obstetrics, 410 Intravenous, in tropics, 431 tribromethylalcohol (avertin bromethal) 432 acute hypertension with sodium pentothal, in neurological surgery 484, military aspects of early analgesia and, 522 mephedrine as pharmacological product for preparing patient for 523 refrigeration, in surgery of extremities, 525

- Anesthetics, Acetaldehyde, volatile and sympathetic stimulation, 34, function of liver as affected by various operations and 344
- Aneurysm, Traumatic, of first portion of left vertebral artery, 57; arterial, following injury to iliac vessels, 199; arteriovenous, of great cerebral vein and arteries of circle of Willis, formation by junction of great cerebral vein and straight sinus and of choroidal arteries, and anomalous branches of posterior cerebral arteries, 187; unilateral vascular compressor for development of collateral blood circulation in arterial and arteriovenous, 55; arteriovenous, 330; surgical treatment of traumatic, 436
- Angiotonin, Studies on hypertension, bioassay of vasoconstrictor substances in ultrafiltrates of citrated blood plasma from patients with normal blood pressures, patients with essential hypertension and patients made hypertensive by intravenous injections of (hypertensin) 173
- Ankle, Roentgen study of, in severe sprains and dislocations, 45; post-traumatic, pure articular calcifications and ossifications of, 30
- Anomalies, Congenital, following maternal rubella, 53; rare, in, 109; 52
- Ascorbic acid, Renal syndrome of wide distribution induced possibly by renal, 54; hazard of during nitrous oxide anesthesia, 6
- Antispasmodic, AP-43, new for use in urology, 45
- Aorta, Thrombosis of, in newborn, 3 cases, with infarction of liver, 38; retrograde arteriography, study of abdominal, and iliac arteries, 57; congenital constriction of and its surgical treatment, 50; coarctation of, 173; surgical correction for coarctation of, 436
- AP-43, New antispasmodic for use in urology, 45
- Apelitis, Study of experimental urinary calculi, quantitative microchemical, spectrographic, and citric acid analyses of albino rat calculi with preliminary report on, 32
- Apomorphine, Utility of, in clinical anesthesia, 340
- Appendicitis, Acute, 26; survey of, 200 consecutive cases, 57; peritonitis due to, 27; salmonella, 7; mortality factors in acute, 7; periolephic abscess, 3 cases simulating acute, 205
- Appendix, Solitary giant follicular lymphoma of vermiform, 84
- Aquinos during labor, effect on prothrombin level of newborn infant, 36
- Arachnoiditis and paralysis following spinal anesthesia, 275
- Arm, Intercarpalothoracic disarticulation of, 33
- Arteries, Retrograde arteriography in study of abdominal aorta and iliac, 57; traumatic aneurysm of first portion of left vertebral, 57; parosymptomatic headache, 60; neurolysis following injury to iliac vessels, 90; clinical differentiation of embolism, retinal, from endarteritis, 353; surgery of disease and injury of, 57
- Artery, Thrombosis of brachial treated with successive cervical sympathectomy blocks, 274
- Arthritis, Gold therapy for rheumatoid, 54; treatment of gonococcal, with sulfonamides and artificially induced fever, 3; beneficial effects of roentgen therapy in advanced cases of rheumatoid, preliminary report, 5
- Arthroscopy, Analysis of, 60 cases of consecutive for traumatic, 1; removal of fragments of knee joint, 40
- Ascorbic acid, Importance of (vitamin C) in chest surgery, 73
- Asus, Medical problems of Command of Southeast, 70
- Asystole, Fatal bronchial showing anaphylactic reaction to, 10; 10; 10
- Atelactasis, Medical treatment of postoperative, 3
- Atomic bomb, Radiation sickness in Nagasaki, preliminary report, 53
- Atrophy, Calvarian and denervated muscle, 226
- Averin, Tribromethyl alcohol (bromethol), 437
- BACILLURIA, Tubercle, 37**
- Bacillus histolyticus, Occurrence of, 1; accidental wounds without recognized specific infection, 69
- Back, Herniation of fascial fat and para lumbar, 40
- Bacteria, Postoperative findings in lower urinary tract after suprapubic prostatectomy, 43; effect of mixtures of ethyl alcohol and ether on, 69; in vitro action of streptomycin on, 52
- Barbiturates, Influence of liver and kidney on duration of anesthesia produced by, 163
- Bed sores, Operative treatment of decubitus ulcer, 39
- Beryllium, Poisoning with, 348
- Biceps, Subcutaneous rupture of distal tendon of musculobrachial cases, 47
- Bile, Streptomycin, absorption, diffusion, excretion and toxicity, 257
- Bile ducts, Uremia in lesions of liver and, 28; variations and anomalies of system of, and its associated blood supply, 25; transpapillary duodenal drainage of hepatic, 15; chronic sclerosing pancreatitis causing complete strictures of common, 15; 4 years of experience with operative cholangiography, 209; use of vitallium tubes in strictures and absence of common, 10; advanced carcinoma of extrahepatic cholangiocholecystocholecystectomy, 21; cystic, in biliary lithiasis, 300; diagnosis of choledocholithiasis, 308; congenital obstruction of, and icterus gravis neonatorum, 399
- Bilharziasis, Of bladder (vesical schistosomiasis), 37; surgical aspects of urinary, 317
- Biliary tract, Fragmentation and dislocation of gall stones by chloroform, 29; 4 cases of acute pancreatitis in previously cholecystectomized patients, results concerning recurrences in 46 cases of acute pancreatitis, 20; chronic sclerosing pancreatitis causing complete stenosis of common bile duct, 5; transpapillary duodenal drainage of hepatic duct, 5; use of vitallium tubes in strictures and absence of common bile duct, 10; advanced carcinoma of extrahepatic bile ducts, cholangiocholecystocholecystectomy, 21; 5 cases of cholecystododenostomy, 202; silent gallstones, 300; internal fistulas of, 493
- Bilirubin, Occurrence, human serum of yellow substances different from bilirubin and carotenoids, 397
- Bilroth, Technique of, and Schoemaker gastrectomy, 29
- Biopsy, Qualitative and quantitative histological examination of material from patients by, after radiation for carcinoma of cervix uteri, 347; clinical value of, 35
- Bladder, Carcinoma of sigmoid and rectosigmoid involving urinary, 9; 40 cases of vesicovaginal fistula, 5; bilharziasis of (vesical schistosomiasis), 137; lat invasion of and prostate by carcinoma of rectum or sigmoid, 138; treatment of dysfunction of after neurological trauma, 223; contact roentgen therapy in cancer of, 250; cystostomy, 314; surgical aspects of urinary bilharziasis, 317; study of experimental urinary calculi, methods for producing and preventing calculus formation in, and ureters of albino rats, 230; histology of human urinary, 413; treatment of tumors of urinary, 300; prevention and treatment of delayed wound healing and ulcerative cystitis following surgery for tubererculous of genitourinary tract, 300
- Blast, Resection of human conduction mechanism in, 60; mechanism of injuries due to, 57; injuries of ear due to, 324; 1; injury of personnel due to, 434

SUBJECT INDEX

- Blindness, Denial of by patients with cerebral disease, 7
- Blood, Aquinone during labor effect on prothrombin level of newborn infant, 36 prothrombin index after operation, 58 heparin content of in clinical thrombosis, 59 results of routine investigation for Rh factor, 59 hemolytic crises in congenital hemolytic disease, 61 antithrombotic action of gelatin, 84 hemolytic disease of newborn (erythroblastosis fetalis) 130 leucemoid reaction of stimulating acute aleukemic leukemia in case of phlegmonous gastritis, 153 attempted transmission of human leukemia in man, 153 aural manifestations of leukemia, 179 aplastic anemia terminated by removal of mediastinal tumor 196 observed on pulmonary arterial pressure and peripheral circulation following arterial ligation of 234 rationale of therapy with whole, 199 excretion and toxicity of mycin absorption, diffusion on adenine equivalent of further observations on adenine injury 262 of rabbits following lethal forms of tissue injury 262 traumatic shock incurable by volume replacement of megakaryocytes in idiopathic thrombocytopenic purpura, a form of hyperphenism, 300 iodine studies of 348 etiology and treatment of polythemia rubra vera, 348 value of penicillin in treatment of agranulocytosis caused by thiouracil 348 hypoproteinemia in surgery of thorax, 394 anemia of newborn, 410 Rh factor cause of fetal erythroblastosis, hemolytic disease of newborn and transfusion reactions, 437 burns, collective review 443, thiouracil as cause of neutropenia and agranulocytosis, 481
- Blood pressure, In normal pregnancy 33 studies on hypertension bioassay of vasoconstrictor substances in ultrafiltrates of filtered blood plasma from patients with normal patients with essential hypertension and patients made hypertensive by intravenous injections of angiotensin (hypertension) 173 observations on pulmonary arterial, and peripheral venous, following arterial blood loss, 234 of relatives of patients with toxemia of late pregnancy preliminary results 300 of late pregnancy preliminary results 300 of late pregnancy preliminary results 300 of late pregnancy preliminary results 300
- Blood transfusion And anemic heart 60 hemolytic reactions following due to Rh factor 3 cases, 61 Rh factor cause of fetal erythroblastosis, hemolytic disease of newborn, and reactions due to, 437 intracardiac, 517 influence of sex in reactions from, 518
- Blood vessels, Retrograde arteriography in study of abdominal aorta and iliac arteries, 57 thrombosis following leg injuries, 58 variations and anomalies of biliary duct system and its associated blood supply 123 congenital coarctation of aorta and its surgical treatment, 150 thromboembolism following ligation of iliac vessels, 150 thromboembolism 151 ligation mode of production of pulmonary embolism of inferior vena cava for prevention of pulmonary embolism, 153 coarctation of aorta, 173 arteriovenous aneurysm of great cerebral vein and arteries of circle of Willis, formation by junction of great cerebral vein and straight sinus, and of choroidal arteries, 187 aneurysm branches of posterior cerebral arteries, 5 cases, 193 surgical therapy on patent ductus arteriosus, 5 cases, 193 failure of surgical treatment in case of thrombophlebitis of splenic vein 212 secondary hemorrhage arising from gunshot wounds of peripheral 234 universal blood from gunshot wounds for development of aneurysms, circular compressor for development of aneurysms in relation to circulation in arterial and arteriovenous aneurysms 235 problem of portal hypertension in relation to hepatomegaly, 236 technique of using vitallium tubes in establishing portacaval shunts for portal hypertension 237 blood supply of peripheral nerves, practical consideration 271 surgical relief for intracranial obstruction from vascular ring 283 arterial circulation of stomach, gastric hemorrhage, 290 transection of stomach, 330 arteriovenous aneurysm 330 studies in experimental vascular surgery, 331 use of radioactive sodium as tracer in study of peripheral vascular disease 346 blood supply of sciatic nerve and its popliteal division in man 383 surgical correction for coarctation of aorta, 416 surgical treatment of traumatic aneurysms, 426 surgery of arterial disease and injury 517 anatomy of human lung as applied to chest radiology 528
- Boeck's sarcoid, Relationship of and tuberculous case in which tuberculosis of lymph nodes was associated with features highly suggestive of 440
- Bone, Atrophy of osteoarthritis 46, experiences with hypertrophic osteoarthritis in World War II, 46 echinococcosis of 48 nailing in marrow cavity in cases of recent fracture and pseudarthrosis 28 cases, 52; epidemiology of acute poliomyelitis in India Command, 55 osteomyelitis caused by granuloma inguinale in port of case with cultivation of Donovan bacillus in yolk sac of developing chick embryo, 144 "bone chip" grafts in defects of long 145 iliac hernia after bone grafting 145 surgical treatment of pathological fractures, 148 mechanical and biological problems in nailing marrow of fractured, by Kuentzsch's method, 148 cancellous transplants of, for correction of saddle nose, 155 treatment of benign giant cell tumor in lower third of femur by curettage and "telescoping," fragments of 230 growth of in congenital myxoidema, 232 tumors in 1 of homologous twins, Hodgkin's disease with primary skeletal manifestations, 239 case acute hematogenous osteomyelitis become less common and less severe, 322, penicillin in treatment of chronic osteomyelitis, preliminary report, 322 recent interpretation of acute hematogenous osteomyelitis treated with penicillin 322 surgical obliteration of cavities of, following traumatic osteomyelitis, 325 recognition of primary hyperparathyroidism, 326 significance of internal frontal hyperostosis and some related changes of skeleton, with special reference to diabetes in aged 329 osteitis pubis following prostatectomy, 415 chronic sclerosing osteitis, 430 use of penicillin in treatment of acute hematogenous osteomyelitis in children 430 mutational dysostosis (osteodysplasia) 432 method of treatment of chronic infective osteitis, 433 transplantation of iliac, preliminary observations, 434 penicillin treatment of acute hematogenous osteomyelitis, 430 sarcoma complicating Paget's disease of 516 use of cancellous chips in grafting of 512 incidence of complications in use of transfixion pins and wires for traction of 513 alveolar and failure of union after fractures and osteomyelitis of proximal or trochanteric end of femur 515 roentgen picture of tuberculous arthropathies and affections of 527
- Boeck's, Pathogenesis of localized fibrous lesions in metastases of lung, 422 congenital absence of radius, 423 attempts to localize tumor metastases in lung, by mechanical trauma, 441
- Brachymetopody 327
- Brachycephalus, 6 denial of blindness by patients with cerebral disease, 7 experiences with 156 penetrating wounds of head 7 diagnosis and treatment of strictures of aqueduct of Sylvius (causing hydrocephalus) 7 fibrin film, 8 electroencephalogram of dogs with experimental space-occupying intracranial lesions, 10 cerebral fat embolism after electrical convulsion therapy 1 degenerative effects of large doses of

- Anesthetics, Acetaldehyde volatile, and sympathetic stimulant, 341 function of liver as affected by various operations and, 344
- Aneurysm Traumatic, of first portion of left vertebral artery 57 arterial, following injury to iliac vessels, 50, arteriovenous, of great cerebral vein and arteries of circle of Willis, formation by junction of great cerebral vein and straight sinus and of choroidal arteries and anomalous branches of posterior cerebral arteries, 87 universal vascular compressor for development of collateral blood circulation in arterial and arteriovenous, 235 arteriovenous, 330 surgical treatment of traumatic, 486
- Angiotensin, Studies on hypertension, bioassay of vasoconstrictor substances I ultrafiltrates of citrated blood plasma from patients with normal blood pressures, patients with essential hypertension, and patients made hypertensive by intravenous I injections of, (hypertension) 173
- Ankle Roentgen study of in severe sprains and dislocations, 148 post traumatic peri-articular calcifications and ossifications of 230
- Anomalies, Congenital following maternal rubella, 33 rare, I elbow 5
- Anoxia, Renal syndrome of wide distribution induced possibly by renal, 34 hazard of during nitrous oxide anesthesia, 162
- Antihypertensive, AP-43, new for use in urology 45
- Aorta, Thrombosis of in newborn 3 cases, 1 with infarction of liver 36 retrograde arteriography in study of abdominal, and iliac arteries, 97 congenital coarctation of and its surgical treatment, 90 coarctation of 73 surgical correction for coarctation of, 486
- AP 43, New hypotensive for use in urology 45
- Apallite Study of experimental urinary calculi quantitative microchemical, spectrographic, and citric acid analyses of albino rat calculi, with preliminary report on 321
- Apomorphine Utility of, in clinical anesthesia, 340
- Appendicitis, Acute, 16 survey of 2,000 consecutive cases, 27 peritonitis due to, 27 salmonella, 7 mortality factors in acute 7 perinephric abscess, 3 cases simulating acute 208
- Appendix, Solitary giant follicular lymphoma of vermiform, 84
- Aquinos during labor effect on prothrombin level of newborn infant, 96
- Arachnoiditis and paralysis following spinal anesthesia, 275
- Arm, I tenodesiorthotic disarticulation of 33
- Arteries, Retrograde arteriography I study of abdominal aorta and iliac, 57 traumatic aneurysm of first portion of left vertebral, 57 paroxysmal headache, 90 aneurysm following I injury to iliac vessels, 90 clinical differentiation of emboli in rethral from endarteritis, 383 surgery of disease and I injury of 57
- Artery Thrombosis of brachial, treated with successive cervical sympathetic blocks, 74
- Arthritis, Gold therapy for rheumatoid, 54, treatment of rheumatoid, 15th sulfonamides and artificially induced fever 5 beneficial effects of roentgen therapy in advanced cases of rheumatoid preliminary report, 5
- Arthroscopy Analysis of 90 cases of consecutive for traumatic internal derangement of knee joint, 40
- Ascorbic acid, Importance of (vitamin C) in chest surgery 73
- Asia, Medical problems of Command of Southeast, 70
- Asthma, Fatal bronchial showing asthmatic reaction in ovarian teratoma, 7
- Atelectasis, Medical treatment of postoperative, 9
- Atomic bomb, Radiation sickness in Nagasaki preliminary report, 331
- Atrophy Galvanism and denervated muscle, 226
- Avartin, Trifluoromethyl alcohol (trifluoromethanol) 432
- BACILLURIA, Tubercle 37
- Bacillus histolyticus, Occurrence of in accidental wounds without recognized specific infection, 169
- Back Herniation of fascial I and pila low in, 40
- Bacteria, Postoperative findings in lower urinary tract after suprapubic prostatectomy 45 effect of mixtures of ethyl alcohol and water on 60 I vitro action of streptomycin on 5
- Barbiturates, Influence of liver and kidney on duration of anesthesia produced by 62
- Bed sores, Operative treatment of decubitus ulcer 59
- Beryllium, Poisoning with, 348
- Biceps, Subcutaneous rupture of distal tendon of musculus brachialis, 47
- Bile, Streptomycin, absorption diffusion, excretion, and toxicity, 57
- Bile ducts, Uremia in lesions of liver and 28 variations and anomalies of system of and its associated blood supply 13 transpapillary duodenal drainage of hepatic, 5 chronic sclerosing pancreatitis causing complete stenosis of common, 157 4 years of experience with operative cholangiography 200 use of vitallium tubes I strictures and absence of common, 9, advanced carcinoma of extrabiliary cholangiocystocholedochectomy, cystic, I biliary fistulae, 300; diagnosis of choledocholithiasis, 303 congenital dilatation of, and leturus gravis neonatorum, 197
- Bilharziasis, Of bladder (vesical schistosomiasis) 137 surgical aspects of urinary 37
- Biliary tract, Fragmentation and dislocation of gall stones by chloroform, 29 4 cases of acute pancreatitis in previously cholecystectomized patients remarks concerning recurrences I 46 cases of acute pancreatitis, 39 chronic sclerosing pancreatitis causing complete stenosis of common bile duct, 125 transpapillary duodenal drainage of hepatic duct, 25 use of vitallium tubes I strictures and absence of common bile duct, 9 advanced carcinoma of extrabiliary bile ducts, cholangiocystocholedochectomy 2 5 cases of cholecystodochodochectomy 202 silent gallstones, 309 internal fistulas of, 493
- Bilifundia, Occurrence in human serum of yellow substances different from bilirubin and carotenoids, 397
- Bilroth, Technique of and Schoemaker gastrectomy 21
- Biopsy Qualitative and quantitative histological examination of material from patients by, after radiation for carcinoma of cervix uteri, 347 clinical value of muscle 351
- Bladder Carcinoma of sigmoid and rectosigmoid involving urinary 9 40 cases of vesicovaginal fistulae, 5, bilharziasis of (vesical schistosomiasis) 137 late invasion of, and prostate by carcinoma of rectum or sigmoid, 38 treatment of dysfunction of after neurological trauma, 23 contact roentgen therapy in cancer of 50 cystoscopy 3 4 surgical aspects of urinary bilharziasis, 37 study of experimental urinary calculi, methods for producing and preventing calculus formation in, and urethra of albino rats, 200 elasticity of human urinary 43 treatment of tumors of urinary 206 prevention and preventing calculus formation and ulcerative cystitis following surgery for tuberculous of genitourinary tract, 200
- Blast, Reaction of human conduction mechanism to, 90 mechanics of injuries due to, 157-1 series of ear due to, 384, I injury of personnel due to, 424

- Blindness, Denial of by patients with cerebral disease 7
- Blood, Aquinone during labor: effect on prothrombin level of newborn infant, 36 prothrombin index after operation, 58 heparin content of in clinical thrombosis, 59 results of routine investigation for Rh factor 59 Ia hemolysis in congenital hemolytic disease 61 hemolytic transfusion reactions due to Rh factor 2 cases, 61 antithrombotic action of gelatin 84 hemolytic disease of newborn (erythroblastosis fetalis) 130 leukemoid reaction of stimulating acute aleukemic leukemia in case of phlegmonous gastritis, 153 attempted transmission of human leukemia in man 153 aural manifestations of leukemia, 170 aplastic anemia terminated by removal of mediastinal tumor 196 observations on pulmonary arterial pressure and peripheral venous pressure following arteriotomy of 234 rationale of therapy with whole in severe burns, 241 atropine absorption, diffusion excretion and toxicity 257 further observations on adenine equivalent of rabbits following lethal forms of tissue injury 262 traumatic shock incurable by volume replacement therapy, 262 megakaryocytes in idiopathic thrombocytopenic purpura a form of hypenplasia, 300 iodine studies of 348 etiology and treatment of polycythemia rubra vera, 348 value of penicillin in treatment of agranulocytosis caused by thiouracil 348, hypoproteinemia in surgery of thorax, 394 anemia of newborn 410 Rh factor cause of fetal erythroblastosis, hemolytic disease of newborn and transfusion reactions, 427 burns collective review 443, thiouracil as cause of neutropenia and agranulocytosis, 481
- "Blood pressure. In normal pregnancy 33 studies on hypertension bioassay of vasoconstrictor substances in ultrafiltrates of filtrated blood essential hypertension and patients made hypersensitive by intravenous injections of angiotensin (hypertensin) 173 observations on pulmonary arterial and peripheral venous, following arterial blood flow, 234 of relatives of patients with toxemia of late pregnancy: preliminary note 400
- Blood transfusion. And anemic heart 60 hemolytic reactions following due to Rh factor 2 cases, 61 Rh factor cause of fetal erythroblastosis, hemolytic disease of newborn, and reactions due to, 427 intracardiac, 57 influence of sex in reactions from 518
- Blood vessels, Retrograde arteriography in study of abdominal aorta and iliac arteries, 57 thrombosis following leg injuries, 58 variations and anomalies of biliary duct system and its associated blood supply 123 congenital coarctation of aorta and its surgical treatment, 150 arterial aneurysm following injury to iliac vessels, 150 thromboangiitis obliterans, 151 iliac vessels, 150 thromboangiitis emboli 151 ligation mode of production of pulmonary embolism of inferior vena cava for prevention of pulmonary embolism, 152, coarctation of aorta, 173 arteriovenous aneurysm of great cerebral vein and arteries of circle of Willis formation by junction of great cerebral vein and straight sinus, and of choroidal arteries, 187 surgical branches of posterior cerebral arteries 5 cases, 193 glial therapy on patent ductus arteriosus in case of thrombophlebitis of surgical treatment in case of thrombophlebitis of splenic vein, 112 secondary hemorrhage arising from gunshot wounds of peripheral 254 unilateral vascular compressor for development of collateral blood circulation in arterial and arteriovenous aneurysms, 235 problem of portal hypertension in relation to hepatosplenopathies, 236 technique of using vitallium tubes in establishing portocaval shunts for portal hypertension 237, blood supply of peripheral nerves, practical considerations, 271 surgical relief for tracheal obstruction from vascular ring 283 arterial circulation of stomach, gastric hemorrhage 290 traumatic vasospastic disease 330 arteriovenous aneurysm 330 studies in experimental vascular surgery, 331 use of radioactive sodium as tracer in study of peripheral vascular disease 346 blood supply of sciatic nerve and its popliteal divisions in man, 388 surgical correction for coarctation of aorta, 426 surgical treatment of traumatic aneurysms, 426 surgery of arterial disease and injury 517 anatomy of of human lung as applied to chest radiology 528
- Brock's sarcoma, Relationship of and tuberculosis case in which tuberculous of lymph nodes was associated with features highly suggestive of 440
- Bone Atrophy of terminal phalanges in clubbing and hypertrophic osteoarthropathy 46, experiences with injuries and diseases of in World War II 46 echinococcosis of 48 nailing in marrow cavity in cases of recent fracture and pseudarthrosis, 28 cases, 52 epidemiology of acute poliomyelitis in India Command 55 osteomyelitis caused by granuloma inguinale report of case with cultivation of Donovan body in yolk sac of developing chick embryo, 144 "bone chip" grafts in defects of long 145 iliac hernia after bone grafting 145 surgical treatment of pathological fractures, 148 mechanical and biological problems in nailing marrow of fractured, by Kuentzner's method, 148 cancellous transplants of, for correction of saddle nose, 155 treatment of benign giant cell tumor in lower third of femur by curettage and "telescoping" fragments of 230 growth of in congenital myxodema, 232 tumors in 2 of homologous twins, Hodgkin's disease with primary skeletal manifestations, 230 has acute hematogenous osteomyelitis become less common and less severe, 322, penicillin in treatment of chronic osteomyelitis, preliminary report, 322 roentgenographic interpretation of acute hematogenous osteomyelitis treated with penicillin, 322 surgical obliteration of cavities of, following traumatic osteomyelitis, 323 recognition of primary hyperparathyroidism and 326 significance of internal frontal hyperostosis and some related changes of skeleton, with special reference to diabetes in aged 389 osteitis pubis following prostatectomy, 415 chronic sclerosing osteitis, 430 use of penicillin in treatment of acute hematogenous osteomyelitis in children, 430 mutational dysostosis (cleidocranial dysostosis) 431 method of treatment of chronic infective osteitis, 433 transplantation of iliac; preliminary observations, 424 penicillin treatment of acute hematogenous osteomyelitis, 430 sarcoma complicating Paget's disease of 510 use of cancellous chips in grafting of 512 incidence of complications in use of transfusion pins and wires for traction of 513 slowness and failure of union after fractures and osteotomies of proximal or trochanteric end of femur 515 roentgen picture of tabetic arthropathies and affections of 527
- Bones, Pathogenesis of localized fibrous lesions in metaphyses of long 422 congenital absence of radius, 423 attempts to localize tumor metastases in long, by mechanical trauma, 441
- Brachymetopody 335
- Brain, Pneumococcal, 6 denial of blindness by patients with cerebral disease, 7 experiences with 156 penetration of head, 7 diagnosis and treatment of trating wounds of aqueduct of Sylvius (causing hydrocephalus) 7 fibrin film, 8 electroencephalogram of dogs with experimental space-occupying intracranial lesions, 10 cerebral fat embolism after electrical convulsion therapy 11 degenerative effects of large doses of

- roentgen rays on burnae, 97; treatment of bilateral retinoblastoma (retinal glioma) surgically and by radiation, report on progress, 98; lumbar puncture in treatment of penetrating wounds of, 98; electroencephalographic localization and differentiation of lesions of frontal lobes, pathological confirmation, 186; prefrontal leucotomy: ten cases, 186; arteriovenous aneurysm of great cerebral vein and arteries of circle of Willis: formation by junction of great cerebral vein and straight sinus, and of choroidal arteries and anomalous branches of posterior cerebral arteries, 187; roentgen therapy of primary neoplasms of and stem of, 249; radiological aspects of intracranial pneumocephalus, 272; new type of pedunculate syndrome: anterior nuclear ophthalmoplegia and bilateral cerebellar syndrome caused by segmental lesion, 71; disseminated oligodendroglioma, 273; tumors of third ventricle: personal experience in 5 cases, 272; penetrating cranial wounds, summary of methods used in management: collective review, 333; multiplicity of representation versus punctate localization in motor cortex: experimental investigation, 359; disturbances in sleep mechanism: clinicopathological study: lesions at corticodiencephalic level, 399; surgical relief of tremor at rest, 391; punctate hemorrhage of following thoracic trauma, 489.
- Breast.** Treatment of carcinoma of, 1; osteoid sarcoma of complication of fibroadenoma, 83; prognosis of papilloma of lactiferous ducts, 1; unusual aspects of cancer of 190; cancer of with special reference to results of different methods of treatment, 90; etiological consideration concerning cancer of, 276; adenolipoma and lipoma of 391; 3 cases of mixed tumor of 457.
- Bronchiectasis.** Treatment of with chemotherapy and allergy management, 93.
- Bronchoscopy.** Reactions following, 203; spontaneous pneumothoraces occurring in patients undergoing peroral endoscopy, 276.
- Bronchitis.** Cylindroma of, 278.
- Brucellosis.** Osteoarticular lesions in 429.
- Burns.** Cleansing of oil-covered skin and, 63; therapy of 66; treatment of plea for simplicity, 67; first aid for phosphorus, 68; rationale of whole blood therapy 1; severs, 241; -ray from fluoroscopy of gastrolatent tract, 249; metabolic alterations following thermal, 254; effect of local anesthetics on cell division and migration following thermal, of cornea, 266; routine for early skin grafting of deep, 335; principles in early reconstructive surgery of severe thermal, of hands, 429; dermatome skin grafts for: in patients prepared with dry dressings and with and without penicillin, 429; standardized procedure for back, in white rat suitable for study of effects of therapeutic and toxic agents on long term survival, 44; collective review 443.
- CALCIFICATIONS.** Study of periscapulothoracic, 45; post-traumatic para-articular and ossifications of ankle, 290.
- Calcium.** Studies on patients convalescent from fractures: urinary excretion of, and phosphorus, 327.
- Calculus.** Studies: urinary 43.
- Calculus.** Urinary lithiasis: childhood clinical study of 7 cases of urinary in children, 50; pancreatic; report of 3 cases 1; young adults, 21; cystoscopic treatment of in ureter with special reference to larger; based on study of 530 cases, 27; lumbar ureterolithotomy; Foley operation, 3; urinary 380; study of experimental urinary: methods for producing and preventing formation of 1; bladder and urethra of albino rats, 340; study of experimental urinary: quantitative microchemical spectrographic, and citric acid analyses of albino rat, with preliminary apertis report, 22; recognition of primary hyperparathyroidism, 356; diagnosis of choledocholithiasis, 293; silent gallstones, 399; renal calculi associated with hyperparathyroidism, 48.
- Calvarium.** Radiation necrosis in living: report of 3 cases, 76.
- Cancer.** Of face: 1 of oral cavity 4; treatment of, of maxilla, 12; short oesophagus (thoracic stomach) and association with peptic ulceration and, 5; pancreatobronchoductectomy for of ampulla and ampullary region, 30; results of treatment in series of cases of, of cervix, 50; of uterine cervix, 50; of cervix complicated by pregnancy 33; treatment of of prostate by irradiation, 211; cancerous synovial tumors, 47; pulmonary metastasis of diagnosed by bronchoscopy 104; proximal extension of of lung in bronchial, 22, 104; search for asymptomatic gastric, in 500 apparently healthy men of 45 and over, 22; of sigmoid and rectosigmoid involving urinary bladder 9; surgical treatment of, of rectum, 250; resection of duodenum and head of pancreas for primary of head of pancreas and ampulla of Vater 227; 1st invasion of bladder and prostate by carcinoma of rectum or sigmoid, 128; hypertrophic gastritis simulating gastric, 66; transitional epithelial cell, of nasopharynx, 82; of lip: clinical study of 778 cases with particular regard to predisposing factors and radium therapy 182; discussion on treatment of, of larynx, 283; of breast, 11th special reference to results of different methods of treatment, 299; some normal aspects of of breast, 299; of oesophagus: survey of 323 cases, 25; advanced, of extrahepatic bile ducts, cholesystectomycholecystocolicostomy 1; of female urethra; review of literature and report of 3 cases, 215; primary, of ureter with special reference to hydro-nephrosis, 223; contact roentgen therapy in, of bladder 50; direct irradiation of of stomach and other viscera exposed temporarily at operation 250; mortality of and marital status; analysis of deaths attributed to, among white population of New York City during 1930-4, 256; of larynx; significance of histopathological study of serial sections, preliminary report, 269; etiological consideration concerning, of breast, 276; radical resections of advanced intra-abdominal, 293; treatment of of cervix with interstitial radium needles at Rhode Island Hospital, 305; bilateral ovarian, in fetus 30 weeks old, 305; bilateral adrenalectomy in prostate, 30; qualitative and quantitative histological examination of biopsy material from patients treated by radiation for of cervix, 227, 247; carcinogenicity of p-dimethylaminoazobenzene in diets containing fatty acids of hydrogenated coconut oil or corn oil, 349; surgical problems of in lymph nodes, 349; of lung with initial neurological symptoms, 293; primary anastomosis in, of colon, 368; method of transplanting pancreatic duct into jejunum in Whipple operation for of pancreas, 401; malignant tubular adenoma in horned kidney: significance with regard to general pathology of 2; primary of ureter 412; observations on, of prostate treated with estrogenic, demonstrated by serial biopsies, 4; 5; roentgenologically examined case of of thyroid gland, 434; certain effects of dietary fats on production of liver tumors in rats fed p-dimethylaminoazobenzene, 440; in relation to usages, 3 new types in India, 440; attempts to localize tumor metastases in long bones by mechanical trauma, 44; 3 mixed malignant tumor of breast, 5 cases, 487; clinical results with rotation therapy in, of

SUBJECT INDEX

- esophagus, 488 multiple, of colon, 491 of rectum with special reference to sphincteric control, 491 pan-
 creatic insular (neuroblastoma) with generalized metastases, 494 investigation into time factor in roentgen irradiation of cells of 531
 Cannon's point, Significance of in normal and abnormal functions of colon 25
 Capillaroscopy in toxemias of pregnancy with special reference to differential diagnosis, 408
 Carbohydrates, Burns, collective review 443
 Carbuncle, Renal, new method of treatment, 135
 Carotid body Tumors of 83
 Carotid sinus, Syndrome of, relieved by operation 99
 Carriers, Problem of hemolytic streptococcus, in hospital personnel, 439
 Cartilage Neglected septal graft, with experimental observations on growth of human grafts of 481
 Casein, Effects upon small intestine of rapid intravenous injection of casein hydrolysate, 205
 Casts, Burns' collective review, 443 treatment of compound fracture and closed plaster method 513
 Cataracts, Congenital, following rubella in pregnancy 383
 Catgut, Use of fine chronic, for postpartum perineal repair 35
 Catheterization, Urinary stasis and pains after cystoscopy with, of ureters, 311
 Caudal analgesia, Five years' experience with, in private obstetric practice, 71, in obstetrics, with special reference to repeated single blocks, 133 continuous, in obstetrics on trial, 133 continuous, in curettage for abortion, 163 roentgenological study of male sacrum and aid in 163
 Cecum, Solitary diverticulitis of 116 clinical significance of deformity of in amebiasis, 396
 Cells, Effects of crude and purified penicillin on continuous cultures of normal and malignant, 264
 Cerebrospinal fluid, Transfer of penicillin into following parenteral administration, 10 streptomycin absorption, diffusion, excretion and toxicity 257
 Cervix, Carcinoma of uterine, 30, results of treatment indicated by pregnancy 33, pregnancy in, 33 observation on certain rheological properties of human secretions of 304 treatment of carcinoma of, with interstitial radium needles at Rhode Island Hospital, 305 qualitative and quantitative histological examination of biopsy material from patients treated by radiation and contribution to medical statistics coming from Brazil, 406
 Cesarean section, Mortality in 34 placenta accreta in duplex uterus found at, 34
 Chancroid, Diagnosis of 414
 Chemotherapy Treatment of bronchiectasis with, allergy management, 103 streptomycin absorption, excretion and toxicity 257 absorption, excretion and toxicity of streptomycin by means of local, with primary closure of septic wounds by drainage and irrigation cannulae, 339 reactions to penicillin, 340- burns collective review 443 chemoprophylaxis, 319 role of in wounds and surgical infections, 519
 Chest, Relieving thoracoplasty 18 combined injuries of and abdomen, 79, management of intrathoracic and thoracoabdominal wounds in combat zone, 80 postoperative complications of, controlled study in hernia and meniscectomy operations, 101 management of traumatic pyothorax, 104 acute pericarditis, 106 importance of ascorbic acid (vitamin C) in surgery of 175 studies in oleothorax, bacteriostatic action of on tubercle bacillus, 175 Indications for surgery in penetrating wounds of, 193 Immediate care of wounded, 197 review of patients with intrathoracic disease and injury treated on surgical service of U. S. Army General Hospital in North Africa, 198 thoracoabdominal experimental injuries, 212 use of free omental grafts in experimental study 261 spontaneous pneumothoraces occurring in patients undergoing peroral endoscopy 276 experimental hemothorax, 277 traumatic wet lung, 277 penicillin in pulmonary resection 278 use of blood plasma for filling pleural space following total pneumocentesis 279, pericarditis, 281 use and control of moosectomy 281 auxiliary surgical group, thoracic surgical teams of auxiliary surgical group, 283 putrid empyema, 293 hypoproteinemia in surgery of thorax, 304 thoracoabdominal wounds in war 487, punctate cerebral hemorrhage following trauma of 489
 Children, Proctological problems of pediatrician 302 hy-
 droelectrolysis in infancy: cause of urinary retention intestinal obstruction and edema of lower extremities, 404
 Chloroform Fragmentation and dissolution of gallstones by 29
 Cholangiolitis, Fourteen years of experience with operative 109
 Cholecystitis, Acute suppurative and gangrenous, 122 ad-
 ditional test helping in diagnosis of choleic type of 290
 Choroid Tuberculosis of with inclusion of bone tissue 178, epivascular pigment streaks in their pathology and possible prognostic significance, 383
 Chromaffin Tumor of thymus simulating Grave's disease, 536
 Chyuria, Clinical, laboratory and statistical study of 45
 Circulation Coalescence from surgical procedures, studies of lying and standing, of tremor program of bed exercises and early rising 334 posthypocapnic oliguria, kidney function and collapse of, as cause of posthypocapnic oliguria, 533
 Citrinin Miscellaneous pharmacologic actions caused by 519
 Clostridia, Experiences in prophylaxis and treatment of infections due to, in casualties from invasion of Europe, 158
 Coelocladin Study of 100 cases with positive skin test for 392
 Coelocladinomyositis in southern California report of new endemic area with review of 100 cases, 166
 Coccyx Congenital absence of sacrum and complicating pregnancy 130
 Colitis, Ileostomy and colectomy in chronic ulcerative, 116 amoebic, with special reference to perforation, study of 20 autopsied cases, 204
 Colles' fracture, Penetrating cranial wounds summary of methods used in management, 353 burns, 443
 Colon, Significance of Cannon's point in normal and abnormal functions of 25, surgical management of intussusception of 25, significance of 117 congenital normal functions of 254 observations on large intestine of and rectum in forward areas, 117 congenital or hereditary polyposis of 294 preparation for surgery of bowel perforations, 294 surgery of in forward patients with lesions of 294 surgical results of surgery of battle area, 296 operative results of surgery of neoplastic disease, 297 experimental evaluation of sulfanilamide and sulfathiazole in surgery of 302 primary anastomosis in carcinoma of 306 multiple cancer of 491

- Hodgkin's syndrome. Studies in therapeutic use of radioactive phosphorus, 74
- Hormones. Comparative study of clinical responses of women with hypofunctioning ovaries to 3 methods of combined gonadotropic therapy, 3. pregnancy test with, 32. estrogen-progesterone therapy: new approach in treatment of habitual abortion, 32. endocrine function of spleen and its participation in pituitary adrenal response to stress, 330. conditions in uterine myoma and genesis of menstrual disturbances in myomatous women, 493. some observations on carcinoma of prostate treated with estrogens, demonstrated by serial biopsies, 4. 5. status of bioassay in malignant disease of testicle, 4. 8. burns, collective review, 443. action of synthetic estrogens on metabolism of lipids, 493
- Humerus. Fracture of lower end of, in children, treatment and end results, 5. neurothrosis of shaft of, for amputation at elbow, 386
- Hydrumosis. Acute; brief survey of recent literature, with report of case simulating concealed accidental hemorrhage, 9
- Hydrocephalus. Diagnosis and treatment of structures of aqueduct of Sylvius causing, 7
- Hydrothorax. Primary carcinoma of ureter with special reference to, 3
- Hypertension. Studies on bioassay of vasoconstrictor substances in ultrafiltrates of dialyzed blood plasma from patients with normal blood pressures, patients with essential hypertension, and patients made hypertensive by intravenous injections of angiotonin (hypertensin), 73
- Hyperthyroidism. Alternating and myxedema, 8. marine album partition in, special reference to effect of thiocyanate, 82. use of thiocyanate in treatment of patients with, 50. thiobarbital in treatment of, 263
- Hypochloremia in surgical patients, 334
- Hypophysectomy. Effects of varying degrees of on dog, 441
- Hysterectomy. Vaginal, in management of desmoplasia, test, 39
- I**CTERUS. Familial cases of congenital hemolytic disease, 6. splenectomy for acquired hemolytic, in aged, 6. value of plasma vitals. A determination in differential diagnosis of preliminary report, 30. prevention of homologous serum, 439
- Icterus gravis neonatorum. Congenital obliteration of bile ducts and, 399
- Ititis. Chronic, 1. 6
- Ilium. Hernia at, after bone grafting, 45. transplantation of bone of preliminary observations, 414
- Immersion foot syndrome, 242
- Impetigo. Benzyl penicillin, clinical toxicity and efficacy by mouth in, in newborn infant
- India. Epidemiology of acute polyomyelitis in, 55. cancer in relation to tumors, 3. new types in, 440
- Industrial medicine. Labor management relations, 87
- Infarcts. Roentgen diagnosis of pulmonary, 65
- Infections. Purulent meningitis: use of hypertonic solutions in treatment, 8. transfer of penicillin from cerebrospinal fluid following parenteral administration, 0. gas gangrene: study of 95 cases in evacuation hospital, 63. oral penicillin, 70. penicillin by mouth, 70. penicillin by intramuscular injection, 70. filaritis, 60. oral penicillin, 8. role of, in shock produced by muscle injury, 87. penicillin in, of lungs and bronchi, 103. experimental and clinical studies with sulfacetamide (p-aminobenzoic acid ethylacetamide) toxicity and efficiency in bacillary of urinary tract, 4. major amputation stump: health and disease, 45. superiority of con-

- tinuous intravenous drip for maintenance of effective serum levels of penicillin, comparative studies with particular reference to fractional and continuous intramuscular administration, 156. experiences in prophylaxis and treatment of clostridial, in casualties from invasion of Europe, 58. gas gangrene, 33. cases, with death, treated at forward general hospital in Italy, 128. established surgical, treatment with urea-sulfamide mixture, 59. coccidioidomycosis in southern California, report of new endemic area with review of 60 cases, 169. occurrence of bacillus histolyticus in accidental wounds without recognized specific, 169. toxemia of gas gangrene, 69. 35. cases of tetanus, 69. toxid and antitoxin studies of gas gangrene in man, 69. penicillin levels in serum and in some body fluids during systemic and local therapy, 70. effect of penicillin in experimental intestinal obstruction, 76. skin bacteria: their role in contamination and, of wounds, 340. wound, 344. structural changes in early fibrinosis, 255. vaccination during pregnancy as prophylaxis against puerperal, 97. homologous serum hepatitis and hepatitis (epidemic) due to experimental study of immunity and cross immunity in volunteers: preliminary report, 332. secondary of wounds, 337. of superficial palmar space, 338. clinical tetanus, 338. bacteriology of war wounds in Pacific area, 338. local use of penicillin, 339. penicillin blood levels for 24 hours follow-up single intramuscular injection of calcium penicillin, 1. between oil peanut oil, 340. sulfadiazine prophylaxis and resistant streptococci, 350. numbers and sites of origin of droplets expelled during expiratory activities, 351. penetrating cranial wounds, summary of methods used in management; collective review, 353. study of 60 cases with positive coccidioidin skin test, 30. osteoarticular lesions in brucellosis, 420. penicillin in oil, 430. hepatitis due to, with special reference to its occurrence in wounded men, 450. burns, collective review, 443. rhinopneumonitis (severe granuloma, first case), 1. Tumor, 43. role of chemotherapy in wounds and surgical, 510. treatment of mixed, with penicillin, 530. miscellaneous pharmacologic actions of cistidine, 530. in vitro action of streptomycin on bacteria, 5. malaria in practice of surgery, 1. relationships between malarial and surgical diseases, 534
- Injection. Present status of treatment of hernia by, 64
- Intestine. Healing of tuberculous ulcers of, 24. primary sarcoma of small, 24. intussusception in adults, 23. massive hemorrhage from small, 4. primary malignant disease of small, 5. chronic ileitis, 16. ileostomy and colectomy in chronic ulcerative colitis, 1. 6. effect of penicillin in experimental obstruction of, 76. external hernias containing gangrenous bowel, 307. effects upon small, of rapid intravenous injection of casein hydrolysate, 305. injury of, and fecal fistula in gynecological surgery, 305. regional enteritis, 305. resection operation for gangrenous intussusception in infants, 303. sacrospinobulbourethral and section of, in surgery of large bowel, 309. atypical initial reticuloendotheliosis of jejunum associated with chronic stenosing jejunitis, 303. observations on large bowel perforations, 304. amebic colitis, with special reference to perforation, study of 30 atypical cases, 304. roentgenological and clinical study of duodenal stasis, 305. clinical significance of deformity of cecum in anastomosis, 396. primary anastomosis in carcinoma of colon, 396. re-establishment of pancreatic secretion into, after division of pancreas, experimental study, 400. method of implanting pancreatic duct into jejunum in Whipple operation for carcinoma of pancreas, 40. roentgen

1. Intravenously administered solution of ascule on animals, 263. amebic abscess of opening lat. peritoneal cavity 303. homologous serum hepatitis and infectious (epidemic) hepatitis, experimental study of immunity and cross immunity in volunteers preliminary report, 332. function of as affected by various operations and anesthetics, 344. cystic disease of, 397. roentgen findings in amebic disease of, 436. infectious hepatitis, with reference to its occurrence in wounded men, 439. certain effects of dietary fats on production of tumors of in rats fed p-dimethylaminoazobenzene 440. burns collective review 443.
- Lungs.** Relaxing thoracoplasty 1. penicillin in supportive disease of dust streptococcus hemolyticus, 3. medical treatment of postoperative pulmonary atelectasis, 03. penicillin infection of and bronchi, 1. drainage of cavities 1. bilateral tuberculosis of, 3. treatment of bronchiectasis with chemotherapy and allergy management, 3. metastasis of carcinoma in, diagnosed by bronchoscopy, 104. proximal extension of carcinoma of in bronchial wall, 104. postbronchoscopic reactions, 106. mode of production of emboli in, 51. embolism in, from obscure sources, 15. roentgen diagnosis of infarcts of 105. studies in oleothorax; use of oils in disinfectant oleothorax and in re-expansion of, 1. tuberculosis empyema, preliminary report, 175. closed extrapleural pneumonolysis, 90. resection of in treatment of pulmonary tuberculosis, 19. treatment of abscesses of with penicillin, 93. mucous and salivary gland tumors in bronchi and trachea, 276. traumatic wet, 277. penicillin in resection of, 278. use of blood plasma for filling pleural space following total pneumonectomy 279; operative treatment of fulminant empyemas following pneumothorax, 280. study of 100 cases w. th positive coxidokinin skin test, 308. cancer of with initial neurological symptoms, 393. pneumoconiosis in radiator and boiler fashers, 434. retrolucal fistula, 503. anatomy of blood vessels of humans, as applied to chest radiology 518.
- Luscha's** crypts, Diverticula of gall bladder 401.
- Lymphadenitis.** Acute nonspecific mesenteric, 300.
- Lymph nodes.** Surgical problems of cancer in, 349. relationship of Boeck's sarcoma and tuberculosis; report of case 1. which tuberculosis of lymph nodes was associated with features highly suggestive of sarcoma, 440. burns; collective review 443.
- Lymphogranuloma venereum,** 1. p. experimental transmission of virus of through placenta, 4. 9.
- Lymphoma.** Solitary giant follicular of vermiform appendix, 34.
- Lymphopathia venosa.** Stricture of female urethra w. th, 40.
- Lymphosarcoma** with primary manifestations in gastrointestinal tract 7 cases studied roentgenologically, 4. 7.
- Lymph system.** Urological aspects of filariasis, 44. Hodgkin disease 230. diagnosis of Hodgkin's disease by aspiration biopsy, 33. consideration concerning surgical treatment of elephantiasis of extremities, 333.
- MAGNESIUM.** Partition of, in hyperthyroidism special reference to effect of thionin, 82.
- Malaria.** 1. practice of surgery 1. ter-relationships between infections of and surgical diseases, 534.
- Malignancy.** Primary of small intestine, 5.
- Malnutrition.** Ocular manifestations of in released prisoners of war from Thailand, 265.
- Mandible.** Functional disturbances following fracture of condyle of and their treatment, 9. treatment of gunshot fractures of, 386.
- Marie-Stroempe's disease.** Roentgen irradiation in treatment of (ankylosing spondylarthritis) 66.
- Massage.** Effect of postoperative exercises and, on incidence of pulmonary embolism at Chelsea Hospital for Women, 247.
- Mastitis.** Vitamin C and lactational, 2.
- Mastoidectomy.** Endaural, 5 years' experience, 5.
- Mastoiditis.** Series of 50 cases of acute and subacute, treated by closure of wound and perfusion with penicillin, 91.
- Misc.** For pregnant women, 500.
- Mediastinitis.** Two cases of, caused by perforation of esophagus and treatment with penicillin recovery 287.
- Mediastinum.** Through and through bullet wounds of with recovery 196. aplastic anemia terminated by removal of tumor of 196.
- Medical jurisprudence.** Labor-management relations, 87.
- Megakaryocytes** in idiopathic thrombocytopenic purpura, a form of hyperplasia, 300.
- Meibner's syndrome.** comparison of results of medical and surgical treatment, 180.
- Meningitis.** Purulent, use of hypertonic solutions in treatment, 8. after spinal analgesia, 71. chronic leptomenigeal thickening following treatment of, with salts drugs, 301.
- Mesothorax.** Postoperative chest complications, controlled study in hernia operations and, 101.
- Menstruation.** Studies in amenorrhea, oligomenorrhea, and anovulation, effect of epinephrine and gonadotropin upon establishment of cyclic and ovulation, 1901. hormonal conditions in uterine myoma and genesis of disturbances of, in myomatous women, 405. relation of these cells to disturbances of cycle of, 407.
- Mephedine** as pharmacological product for preparing patient for anesthesia, 533.
- Mesentery.** Acute nonspecific lymphadenitis of, 300.
- Metabolism.** Alterations in, following thermal burns, 254. burns; collective review 443. action of synthetic corticosteroids, of lipids, 493.
- Metastasis.** Dissection of cervical lymph node regions for from malignant tumors of lip, oral cavity and pharynx, 5. pulmonary, of carcinoma diagnosed by bronchoscopy 104. staphylococcal infection of gall bladder 300. attempts to localize tumor, in long bones by mechanical trauma, 44. pancreatic islet carcinoma (pseudoblastoma) with generalized, 494.
- Methionine** in treatment of toxic hepatitis.
- Monkey.** Optimal mating time for pregnancy in, 308.
- Mortality.** Cesarean section, 34. influence of social and economic factors on stillbirths and neonatal deaths, 37. cancer and marital status analysis of deaths attributed to cancer among white population of New York City during 1939-41 256. occurring after operation, 439.
- Mouth.** Carcinoma of oral cavity 43. solitary neuroma of tongue, 268. definitive treatment of maxillofacial injuries, 385.
- Mumps.** Treatment of orchitis of, 4. 8.
- Muscles.** Subcutaneous rupture of distal tendon of brachial biceps, 1. cases, 47. pathology of ruptured pectoralis, 48. role of infection in shock produced by injury of, 87. changes of, in denervation and re-innervation, 276. galvanism and denervated atrophy of 196. solitary myosarcoma, review of 61 cases, 217. acute ischemia of anterior tibial, and long extensor of toes, 250. hernia of 1. report of 6 additional cases in arm and leg, 383. changes in musculature of gastrointestinal tract and in myocardium in progressive dystrophy of, 338. clinical value of biopsies of 351; rupture of rectus abdominis, during pregnancy 30.
- Myelography.** Pantopaque; correlation of roentgenological and neurological findings, 247. pantopaque, for pre-

SUBJECT INDEX

traded discs of lumbar spine 248 entrance of pant
opaque into venous system during 252
Myeloma, Solitary review of 61 cases, 237
Myocardium, Changes in musculature of gastrointestinal
tract and in, in progressive muscular dystrophy, 328
Myxedema, Alternating hyperthyroidism and 81 bone
growth in congenital 232

NAGISAKI Radiation sickness in preliminary report

531
Nasolacrimal duct, Restoration of patency of 382
Nasopharynx, Transitional epithelial cell carcinoma of 182
Neck, Dissection of cervical lymph node regions for meta-
stasis from malignant tumors of lip, oral cavity and
pharynx 5 pulsion diverticulum of hypopharynx at
pharyngoesophageal junction 91 lateral cervical
(bronchial) cysts and fistulas, 94 treatment of collar
stent abscesses of with skin involvement 161 treat-
ment of extensive pharyngostomies following laryn-
gectomy 269 management of recent fracture dislo-
cations of cervical spine, 273
Negroes, Incidence of esophageal disease in 15
Nephritis, Effects of adrenalin and on blood constituents
before and after splenectomy 402
Nephrectomy, Prognosis after; clinical study of early and
late results, 40 prognosis of renal tuberculosis treat-
ment by and outlook of patient considered unsuitable
for operative treatment, 222, partial 310
Nerve block, Anesthesia by combined intravenous pento-
thial sodium and local 72
Nerves, Effects of transient stretching of peripheral 6
experiences with sympathectomy in peripheral lesions, 9,
significance of Cannon's point in normal and abnormal
function of colon 85 hemodynamic and biochemical
changes in dogs subjected to section of spinal cord,
changes in dogs surviving operation for protracted
periods, 85 local fluid loss, stimuli of and (toxin in
perfusion of shock, 85 anterior transposition of pro-
traction paralysis, 186 treatment of bilateral
neural tumors, 187, clinical value of muscle biopsies,
351 traumatic injuries of peripheral analysis of local
desce in 301 consecutive cases of injuries of peripheral
388 blood supply of adrenergic, and popliteal division in
388 histological study of predegenerated autograft of
388 bilateral intracranial section of glossopharyngeal
report of case, 484 acute hypertension with sodium
pentothal anesthesia in surgery of 484
Nervous system, Toxicity of sulfanilamide on higher active
lity of, 188, treatment of bladder dysfunction after
neurological trauma, 223 muscle changes in denerva-
tion and reinnervation, 226 galvanism and denervated
muscle atrophy 226 injuries of spine 273 intra-
articular temperature and thermic criterion of physio-
copyrexia, 345 burns collective review 443 principles
and practice of penicillin therapy in diseases of 456
Neurinoma, Solitary of tongue 268
Neuritis, Peripheral 186 "acroparesthesia" and so-called
of women's hands and arms, 253
Newborn, Anoxemia during labor effect on prothrombin
level of 36 effect on infant mortality of vitamin K
administered during labor 36 effect of respiratory
stimulants in, 36 thrombosis of aorta in 3 cases, 1
with infarction of liver 36 influence of social and
economic factors on stillbirths and deaths of 37 hemo-
lytic disease of (erythroblastosis fetalis), 130 effect of
prediabetic state on survival of fetus and birth weight
of, 130 congenital syphilis in infant treated with peni-
cillin, 31 benzyl penicillin, clinical toxicity and effi-
cacy by mouth in impetigo in 221 congenital anoma-
lies following maternal rubella, 255 anemias of 470

Rh factor cause of fetal erythroblastosis, hemolytic
disease of and transfusion reactions, 427 roentgen ex-
amination in congenital intestinal obstructive defects
in infants, 434

Nitrogen, Burns collective review 443
Nitrous oxide, Hazard of anoxia during anesthesia with, 162
Nose Structure of external study from point of view of
plastic surgery, 3 cancellous bone transplants for cor-
rection of saddle 155 abscess of septum of complica-
tion acute ethmoiditis, 267 genesis of typical and atypic-
cal cysts of floor of 267 neglected septal cartilage
graft (experimental observations on growth of human
cartilage grafts) 481 rhinospiridium secheri granu-
loma first case in Tucuman 481
Nutrition Intravenous, 110 burns collective review 443
Nylon Backing of, for dermatome grafts, 66
Nystagmus, Significance of positional, in otoneurological
diagnosis, 179

OBSTETRICS, Five years' experience with cauda
anesthesia in private practice of 71 early rising in
puerperium 307, spinal analgesia in operative, 410
Oenethyl, Efficacy of (2-methyl-amino-heptane) as vaso-
pressor substance for spinal anesthesia, 163
Oil Cleansing of skin covered with, and burns, 63; cardio-
genicity of p-dimethylaminobenzenes in diets con-
taining fatty acids of hydrogenated coconut, or corn,
349 penicillin in, 430
Oleothorax, Studies in bacteriostatic action of oils on
tubercle bacillus, 175 studies in, use of oils in disin-
fectant, and in re-expansion of lung in tuberculous em-
pyema (preliminary report) 175
Oligodendroglioma, Disseminated 272
Oliguria, Postnecropsal kidney function and circulatory
collapse, cause of postnecropsal, 533
Omentum, Use of free grafts of in thorax experimental
study 261 torsion of great, 494
Operation, Prothrombin index after, 58 transthoracic ap-
proach for traumatic lesions of spleen, 63; mortality
after 420
Orbit, Surgery of anophthalmic, 382 cavernous hemangio-
ma of successfully removed by Shrugue's operation
470
Orchitis, Treatment of, of mumps, 418
Osteitis, Chronic sclerosing, 420 method of treatment of
chronic infective, 423
Osteoma, Capsular of knee joint, 46
Osteomyelitis, Traumatic; report of case with cultivation of
granuloma inguinale, report of case with cultivation of
Dumortier body in yolk sac of developing chick embryo,
144 has acute hematogenous, become less common and
less severe, 322 penicillin in treatment of chronic, pre-
liminary report, 322 roentgenographic interpretation
of acute hematogenous, treated with penicillin, 322;
surgical obliteration of bone cavities following trau-
matic, 325; of petrous pyramid of temporal bone 384
use of penicillin in treatment of acute hematogenous,
in children 420, pyogenic, of spine, differential diagno-
sis through clinical and roentgenographic observations,
422 penicillin treatment of acute hematogenous, 430
Osteosclerosis, Splenectomy in report of case with, 2
old splenomegaly with report of case with, 2
Osteotomies, Slowness or trochanteric end of femur 515
and of proximal of acute suppurative, 180 treat-
ment of chronic suppurative, with penicillin, 480
Otitis media, Treatment of acute suppurative, with peni-
cillin, 480
Otolaryngology In Army 181; penicillin therapy in prac-
tice of 384
Otosclerosis, Influence of pregnancy on 90, early diagnosis
and arrest of (clinical and histological) 181

- Ovaries, Comparative study of clinical responses of women with hypofunctioning, to 2 methods of combined gonadotropic therapy 311; fatal bronchial asthma showing asthmatic reaction in teratoma of 72 bilateral carcinoma of, in fetus 30 weeks old, 303; curability of granulosa cell tumors, 406; relation of these cells to disturbances of menstrual cycle, 497
- Ovulation, Possible use of kymographic tracing instead of endometrial biopsy for determination of 31; studies in amenorrhea, oligomenorrhea, and anovulomenorrhea, effect of equine gonadotropin upon establishment of cyclic menses and, 29; timing of, with basal temperature graphs, 411
- Oxygen, Burns collective review 443

PAGET'S disease, Sarcoma complicating, of bone, 51
Pain, Following injuries of peripheral nerves, 97
Burns, collective review 443; men wounded in battle, 532

- Pancreas, Pancreaticoduodenectomy for carcinoma of ampulla and ampullary region, 50; islet-cell tumors of 126; resection of duodenum and head of, for primary carcinoma of head of, and ampulla of Vater 127; likelihood of report of 2 cases in young adults, 11; re-establishment of secretion of, into intestine after division of experimental study, 400; method of implanting duct of, into jejunum in Whipple operation for carcinoma of 401; tumors of 493; statistical studies of 53 cases of tumors of 493; insular adenoma of first case in Argentina, 494; insular carcinoma of (psedoblastoma) with generalized metastases, 494
- Pancreatitis, Four cases of acute, in previously cholecystectomized patients, recurrence in 46 cases of acute, 29; chronic sclerosing, causing complete stenosis of common bile duct, 25
- Pantopique, Myelography with, correlation of roentgenological and neurological findings, 447; myelography with, protruded discs of lumbar spine, 243; entrance of into venous system during myelography 52
- Papilloma, On prognosis of of lactiferous ducts, 1
- Paraneoplasia, Adrenomedullary syndrome associated with, of organ of Zuckerkandl, 9
- Paralysis, Anterior transposition of peroneal nerve for traction, 86; tourniquet, 88; rehabilitation of patients with total, below the waist, with special reference to making them ambulatory and capable of earning living, 83; arachnoiditis and, following spinal anesthesia, 57; sixth nerve, after spinal anesthesia, 543
- Parathyroid glands, Recognition of primary hyperparathyroidism, 586; renal calculi associated with hyperparathyroidism, 4 8
- Parkinson's syndrome, Surgical relief of tremor at rest, 30
- Pateila, Operation and prognosis in fracture of, 53
- P-dimethylaminobenzene, Carcinogenicity of in diets containing fatty acids of hydrogenated coconut oil or corn oil, 549; certain effects of dietary fats on production of liver tumors in rats fed, 440
- Peanut oil, Penicillin blood levels for 24 hours following single intramuscular injection of calcium penicillin in beeswax and, 340
- Pelvis, Intestinal injury and fecal fistula in gynecological surgery 305; traumatic dislocation of symphysis of pubis by muscle action, 23; hydrometrocolpos in infancy—cause of urinary retention, intestinal obstruction, and edema of lower extremities, 404
- Penicillin, Penetration of in eye, 3; transfer of, to cerebrosplenic fluid following parenteral administration, 0; in suppurative disease of lungs due to streptococcus hemolyticus, 3; for empyema, 3; topical use as bacteriostatic agent for pulsatice treatment of chronic

stasis ulcers of lower extremities, 60; oral, 70; by mouth, 70; by intramuscular infusion, 70; study of types of hypersensitivity induced by 77; effect of on heparin tolerance, 78; oral, 81; bacteriological and clinical observations on treatment of acute ophthalmia of Egypt with sulfonamides and, 89; in otology 91; series of 5 cases of acute and subacute mastoiditis treated by closure of wound and perforation 11th, 9; in infections of lungs and bronchi, 10; in treatment of empyema, 05; congenital syphilis in an infant treated with, 13; oral, in treatment of gonorrhea, 14; by mouth for gonorrhea, 141; treatment of previously untreated acute gonorrhea with, 14; superiority of continuous intravenous drip for maintenance of effective serum levels of comparative studies 11th; reference to fractional and continuous intramuscular administration, 56; treatment of progressive bacterial synergistic gangrene with, 59; observations on continuous intramuscular method of administering, 61; levels of in serum and body fluids during systemic and local therapy 170; effect of in experimental intestinal obstruction, 56; penetration of, into type further studies, 77; treatment of lung abscesses 11th, 92; limitations of in empyema, 702; benzyl clinical toxicity and efficacy by mouth in impetigo in newborn infant, 22; in gonorrhea treatment and control, 5; comparative study of 00 fractures of shaft of femur in which one half were treated with, 231; effects of crude and purified, on continuous cultures of normal and malignant cells, 214; staphylococcal leptomeningitis treated with intracisternal penicillin, 215; in polmonary resection, 78; cases of mediastinitis caused by perforation of esophagus and tracheostomy with, recovery 287; treatment of gonococcal urethritis with single injections of mixtures of beeswax-peanut oil and, 314; retardation and suppression of experimental early syphilis by small doses of, comparable to those used in treatment of gonorrhea, 3 9; in treatment of chronic osteomyelitis preliminary report, 3 2; roentgenographic interpretation of acute hematogenous osteomyelitis treated with, 322; penetration of into joint fluid following intramuscular administration, 328; local use of 339; blood levels of for 24 hours following single intramuscular injection of calcium and, in beeswax and peanut oil, 340; reactions to, 340; value of in treatment of agnathocytosis caused by thionin, 348; penetrating cranial wounds, summary of methods used in management, collective review 353; therapy in practice of otolaryngology 384; use of, in treatment of acute hematogenous osteomyelitis in children, 420; dermatome skin grafts for burns in patients prepared with dry dressings and with and without, 420; in treatment of tetanus, 430; treatment of acute hematogenous osteomyelitis 11th, 430; in oil, 430; treatment of chronic suppurative otitis media 11th, 480; principles and practice of therapy 11th, in diseases of nervous system 486; treatment of salivary infections 11th, 500; for chronic undermining keratosis, 500

Penicillin X, 60

Pemba, Plastic induration of 507

Pentothal, Use of curare in sodium, and nitrous oxide oxygen anesthesia, 70; sodium, use in continuous intravenous anesthesia and method of preserving in solution, 72; anesthesia by combined intravenous sodium, and local nerve block, 72

Percutaneous, Spinal anesthesia 11th, combined 11th eripal narcosis, 342

Pericarditis, 23; acute, 06; treatment of escaped heart, chronic constrictive, 8

- Pericardium, Successful removal of foreign bodies within 380
- Perineum, Use of fine chromic catgut for postpartum repair of 35
- Peripheral nerves, Effects of transient stretching of 6
- polyneuritis after jungle sores, 6 pain following injuries of 97
- injuries of 185 neuritis of 186 immersion foot syndrome, 242 blood supply of practical considerations, 271 traumatic injuries of analysis of incidence in 301 consecutive cases of injuries of 388 butamine flare in evaluation of lesions of 483

- Prostate, Treatment of carcinoma of, by irradiation, 41 late invasion of bladder and, by carcinoma of rectum or sigmoid, 138, transurethral resection of in patients with advanced renal insufficiency 138 glandular nodule in benign glandular enlargement of development and cause, 224
- Prostatectomy Filten foam as hemostatic agent in suprapubic, 49 indications, technique and results in suprapubic, in 250 personal cases, 42 postoperative bacterial findings in lower urinary tract after suprapubic, 43 asepsia in 139 retropubic, new extravesical technique, 315 oeditis pubis following 415
- Prostate gland Bilateral adrenalectomy in cancer of 309 use of thrombin (topical) in control of bleeding associated with surgery of, 315, significance of spontaneous hematuria associated with hypertrophy of 415 some observations on carcinoma of treated with estrogens, demonstrated by serial biopsies, 415
- Prostigmine, Use of in treatment of amenorrhea and pregnancy test, 305
- Protein, Serum, in normal and toxemic pregnancy 132 hypoproteinemias in surgery of thorax 304

- Prothrombin, Index for, after operation, 58
 Pseudarthrosis, Nailing in marrow cavity in recent fracture and report of 23 cases, 53
 Pterygium, Corneal graft operation for recurrent, 583
 Pulse, Traumatic distasts of symphysis, by muscle action, 531
 Puerperium Early extirpation of uterus in persistent atony with postpartum hemorrhage, 35 use of fine chronic catgut for postpartum perineal repair, 35 early rising in, 307, hemorrhage as most frequent cause of maternal death, deaths in, in Brooklyn in 1944, 502
 Pyonephrosis, Voluminous, and treatment, 51
 Pyothorax, Management of traumatic, 104

RADIATION Sickness from, in Nagasaki preliminary report, 531

- Radioactivity, Use of sodium with, as tracer in study of peripheral vascular disease, 346
 Radium, Results of treatment in series of cases of carcinoma of cervix, 30, cancer of lip, clinical study of 778 cases, with regard to predisposing factors and therapy with, 82, treatment of carcinoma of cervix with interstitial, at Rhode Island Hospital, 3051 adamantinomas of jaw with reference to their treatment, 381
 Radius, Congenital absence of, 43
 Raynaud's Disease, Among men, 99 traumatic vasospastic disease, 350
 Rectum, Prostate of, in children, 8, traumatic injuries of, 23 surgical management of injuries of colon and, in forward areas, 17, management of war injuries of extraperitoneal, 118 surgical treatment of carcinoma of, 305 technique and results of primary and second ary pull-through operation after removal of tumors of, and rectosigmoid, 190 late invasion of bladder and prostate by carcinoma of sigmoid, 158 abdominal surgery in evacuation hospital, 404 carcinoma of with reference to sphincteric control, 49
 Refrigeration, Anesthesia by, in surgery of extremities, 55
 Research, Roentgen radiation in biological, 433
 Respiration, Effect of stimulants on, in newborn infant, 36 numbers and sites of origin of droplets expelled during expiratory activities, 551
 Respiratory tract, Plasma-cell tumors of upper part of, 95 burns collective review, 443
 Reticuloendothelial system, Familial crises in congenital hemolytic disease, 6
 Reticuloendothelioma, Atypical initial, of jejunum associated with chronic atrophic jejunitis, 593
 Retina, Technique and clinical value of injections of hyper tonic salt solution into Tenon's space in detachment of, 78
 Retinoblastoma, Treatment of bilateral (retinal glioma) surgically and by irradiation report on progress, 95
 Rheology Observations on certain properties of human cervical secretion, 304
 Rheumatism, Cold therapy for arthritis due to, 34 beneficial effects of roentgen therapy in advanced cases of arthritis due to preliminary report, 551
 Rh factor Results of routine investigation for, 59 hemolytic transfusion reactions due to, report of, cases, 6 cause of fetal erythroblastosis, hemolytic disease of newborn, and transfusion reactions, 437
 Roentgenography Capsular osteoma of knee joint, 461 osteosarcoma of bone, 48, retrograde arteriography in study of abdominal aorta and iliac arteries, 37 fractures of carpal scaphoid, 46 study of ankle in severe sprains and dislocations, 48 study of male scrotum as aid in caudal analgesia, 63 of pulmonary infarcts, 65 value of gastric pneumography in, 165 gall bladder dye (iodophthalic sodium) effect of intravenous in-

jections on coronary flow blood pressure, and blood coagulation, 168 development of diagnosis by, 247 pantopaque myelography: correlation of roentgenological and neurological findings, 247 pantopaque myelography for protruded discs of lumbar spine, 248 lateral demargination of knee joint, diagnostic scope of soft tissue examinations by and vacuum technique demonstration of menisci, 245 aspects of intracranial pneumocephalus, 271 interpretation of acute hemogenous osteomyelitis treated with penicillin, 30 diff ferential diagnosis of tuberculous in joints of extremities, 523 investigation of free gas in peritoneal cavity, 345 penetrating cranial wounds methods used in management collective review, 353 clinical study and, of duodenal stasis, 393 diagnosis of choledocholithiasis, 308 lipiodol intravascular during stereotomography with pulmonary complications, 404, lymphosarcoma, with primary manifestations in gastrointestinal tract, 7 cases studied roentgenologically, 437 of fractured temporal styloid process, 433, case of cancer of thymus gland, 434 pneumoconiosis in radiator and boiler fitters, 434 congenital intestinal obstructive defects I. Intusus, 434, findings in amoebic disease of liver, 436 with oxygen in diagnosis of I. terminal demargination of knee joint, 436 rare anomaly in elbow, 51 canalization of femoral epiphysis according to Deverry, 51 cause of peritonal edema after therapy with sulfanilamide preparations observed by, 517 roentgen picture of tuberc arthritis and affections of bones, 517 observations on technique of phlebography, 538, anatomy of blood vessels of human lung as applied to chest, 538

Roentgen rays, Necrosis of calvarium due to, 5 cases, 76 degenerative effects of large doses of, on human brain, 97 burns from fluoroscopy of gastrointestinal tract, 249 direct irradiation of cancer of stomach and other viscera exposed temporarily at operation, 250 in biological research, 433 tubes for, 437

Roentgen therapy Carcinoma of oral cavity, 4, treatment of carcinoma of prostate by, 41 in uterine fibroids, 74, symposium physical, biochemical, and therapeutic aspects of volume dose, 74 treatment of bilateral retinoblastoma (retinal glioma) surgically and by report on progress, 95, treatment of testes, 65 cases, 190 in treatment of Marie-Straussell's disease (ankylosing spondylarthritis) 66 causes and prevention of edema of larynx due to, 671 on cancer of breast, with reference to results of different methods of treatment, 90 solitary myeloma; review of 6 cases, 227 of primary neoplasms of brain and brain stem, 249, contract, in cancer of bladder, 50 beneficial effects of in advanced cases of rheumatoid arthritis preliminary report, 551 symposium on ankylosing spondylitis, 324, qualitative and quantitative histological examination of biopsy material from patients treated by for carcinoma of cervix uteri, 3471 clinical results with rotation therapy in cancer of esophagus, 438 multiple cancer of colon, 491 treatment of tumors of urinary bladder, 306, plastic infarction of penis, 5071 development of during 50 years, 530 investigation into the factor in, of cancer cells, 531

Rubella, Congenital anomalies following maternal, 555 congenital cataracts following, in pregnancy, 383

SACRUM Congenital absence of, and coccyx complicating pregnancy, 30 roentgenological study of male adult caudal analgesia, 63

Salivary glands, Neuroepithelioid tumors of, 50 mucous tumors and tumors of, in bronchi and trachea, 278 adenolymphoma of, 386

- Salt, Translocation of fluid produced by intravenous administration of isotonic solutions of in man post operatively 256 hypochloremic state in surgical patients, 334
- Sarcoma, Primary of small intestine, 24, osteoid, of breast complication of fibroadenoma, 83 of right auricle 393 5 cases of mixed malignant tumor of breast, 487 primary malignant tumors of retrovesical region with reference to malignant tumors of seminal vesicles case of retrovesical, 506 complicating Paget's disease of breast, 510 investigation into time factor in roentgen irradiation of cancer cells, 531
- Scars, Use of skin flaps in repair of or ulcerative defects over bone and tendons, 158
- Schistosomiasis, Bilharziasis of bladder (vesical) 137
- Sciara, Semile hyaline plaques of 166
- Scleroderma, Esophageal lesions associated with atherosclerosis and, 285
- Semen, Assessment of male fertility by analysis of attempt to standardize methods, 49
- Serum, Protein of in normal and toxic pregnancy 132 penicillin levels in, and in body fluids during systemic and local therapy 170, occurrence in human, of yellow substances different from bilirubin and carotenoids, 397 electrophoretic analysis of in pregnancy and in pregnancy toxemia, 408 prevention of jaundice due to homologous, 439 burns collective review 443
- Sex, Influence of in transfusion reactions, 518
- Shock, Local fluid loss, nerve stimuli and toxins in cause of, 85 early effects on dogs of section of eighth cervical segment of spinal cord and bearing on, 86 role of infection in, produced by muscle injury 87 post traumatic renal injury experimental observations, 253 metabolic alterations following thermal burns, 254 traumatic, incurable by volume replacement therapy 261 burns collective review 443 study of in battle casualties, 533
- Shoulder Lesions of musculotendinous cuff 47 study of periarthrohumeral calcifications, 145 rotational dysostosis (cleidocranial dysostosis) 421 appliance for conservative treatment of acromioclavicular dislocations, 424
- Singue's operation, Cavernous hemangioma of orbit successfully removed by 479
- Sigmoid colon, Carcinoma of, and rectosigmoid involving urinary bladder 119 technique and results of primary and secondary pull-through operation after removal of tumors of rectum and rectosigmoid, 120
- Sinuses, Abscess of nasal septum complicating acute ethmoiditis, 267 war wounds and injuries involving paranasal, 285 dacryodermatitis stimulating dacryocanal-iculitis, 479 neoplasms of both maxillary 481
- Skin, Cleansing of oil-covered, and burns, 63 traumatic osteomyelitis use of grafts of 63 use of whole grafts of, as substitute for fascial sutures in treatment of hemias preliminary report, 64 bacteria of their role in contamination and infection of, clinicopathological study 120 Disturbances in mechanism of, clinicopathological study lesions at corticodiencephalic level, 390 Sodium, Use of radioactive, as tracer in study of peripheral vascular disease, 346
- Sodium pentothal, Acute hypertension from anesthesia with, in neurological surgery, 484
- Sores, Polypneuria after jungle, 6
- Sphincter Cardioresophageal relaxation, 197 carcinoma of rectum with reference to control of 491
- Spinal analgesia, Meningitis after 71 sixth nerve paralysis after 343 in operative obstetrics, 410
- Spinal anesthesia, Continuous caudal analgesia in obstetrics on trial, 133 caudal analgesia in obstetrics with reference to repeated single blocks, 133 efficiency of "oenthyll" (3 methyl-amino-heptane) as vasopressor substance for 163 arachnoiditis and paralysis follow ing 275 pectinate, combined with evipal narcotics, 349
- Spinal cord, Hemodynamic and biochemical changes in dogs subjected to section of changes in dogs surviving operation for protracted periods, 85 early effects on dogs of section of eighth cervical segment of and bearing on shock, 86 tumors of in children, study of 3 cases of ependymoma, 99, rehabilitation of patients totally paralyzed below waist, with reference to making them ambulatory and capable of earning living 188 lesions of spinal epidural space producing compression of, 484
- Spine, Roentgen irradiation in treatment of Marie-Struempell's disease (ankylosing spondylarthritis), 166, pantopaque myelography for protruded discs of lumbar 248 injuries of 273 management of recent fracture dislocations of cervical, 273 symposium on ankylosing spondylitis, 324 pyogenic osteomyelitis of differential diagnosis through clinical and roentgenographic observations, 422 late results of Albee fixation of tuberculosis of 423
- Spleen, Transthoracic operative approach for traumatic lesions of 63 failure of surgical treatment in case of thrombophlebitis of vein of 212 problem of portal hypertension in relation to hepatosplenopathies, 236 megakaryocytes in idiopathic thrombocytopenic purpura, a form of hypersplenism, 300 endocrine function of and its participation in pituitary adrenal response to stress, 350 burns collective review, 443
- Splenectomy For acquired hemolytic jaundice in aged, 61 in chronic nonleukemic myeloid splenomegaly with report of case with osteoclerosis, 212 technique of using vitallium tubes in establishing portacaval shunts for portal hypertension, 237 effects of adrenalectomy and neonatal anaesthesia on blood constituents before and after 409
- Spint, Universal, for deformities of hand, 425
- Spondylarthritis, Roentgen irradiation in treatment of Marie-Struempell disease (ankylosing) 166
- Spondylitis, Symposium on ankylosing, 324
- Sprains, Roentgen study of ankle in severe, and dislocations, 148
- Staphylococcus, Leptomeningitis due to, treated with intrathecal penicillin 272 metastatic infection of gall bladder due to, 300

- Uremia in lesions of liver and bile ducts, 23

- Ureter.** Pathological and anomalous conditions associated with duplication of renal pelvis and, 154; ligation of supernumerary clinical and experimental study 236 cystoscopic treatment of stones 1 with special reference to large calculi, based on study of 1550 cases, 222 primary carcinoma of with special reference to hydromphrosis, 223 urinary stasis and pain after cystoscopy with catheterization of 311; lumbar ureterolithotomy; Foley operation, 312 surgical aspects of urinary lithiasis, 317 primary carcinoma of 413 circumcaval report of case 114 consideration of preoperative diagnosis and successful plastic repair 503 ureteropelvic obstructions in children, 505
- Urethra.** Structure of female with lymphoplastic venous, 40; trichomonas vaginitis infection in male 241 carcinoma of female review of literature and report of 3 cases, 5 epithelioma of, 314 study of experimental urinary calculi methods for producing and preventing calculus formation in bladder and, of albino rats, 320 repair of complete tear of membranous case report and suggested technique for operation, 507
- Urethritis.** Treatment of gonococcal, with 16 injections of penicillin benzene-precipitate oil mixture, 314
- Urinary tract.** Lithiasis in childhood clinical study of 71 cases of calculi in children, 39 AP 43 new 11 spasmodic for use in urology 45 postoperative bacterial findings 1 lower after suprapubic prostatectomy 45 ligation of supernumerary ureter: clinical and experimental study 136 course in young males 115, 140 experimental and clinical studies with sulfadiazide (p-aminobenzenesulfonfylacetylamide) toxicity and efficiency in bacillary infections of, 441 studies in calculi of 42 renal hypoplasia 14 hydrometer and primary stenosis, 21 urinary stasis and pain after cystoscopy with catheterization of ureter, 31 epithelioma of urethra, 314 vesicoureteral reflux accompanied by renal colic, 317 surgical aspects of lithiasis in, 37 calculi 320 study of experimental calculi of quantitated microchemical spectrographic, and citric acid analyses of blood and calculi, with preliminary report 32 significance of streptococci isolated from female 403 circumcaval ureter report of case with consideration of preoperative diagnosis and successful plastic repair 505 ureteropelvic obstructions in children, 505
- Urine.** Chyluria clinical laboratory and statistical study of 45 personal cases observed in Hawaii, 224; significance of spontaneous hematuria associated with hypertrophy of prostate 415
- Urine tubes.** Patency tests of 3 lipiodol intravasation during uroangiography 14 pulmonary complications, 404
- Uterus.** Carcinoma of cervix of 30 results of treatment in series of 40 cases of carcinoma of cervix, 30 placenta accreta in d. plex, found 1 caesarean section, 33 early extirpation of in persistent tony 14 postpartum hemorrhage 35 radiation therapy in fibroids of 74 vaginal hysterectomy in management of decemora of 70 results of anous 1 per of treatment in adenocarcinoma of endometrium, 5 observations on certain rheological properties of human cervical secretion, 304 hypertrophy of 141 axial torsion of myometrium and pregnant, 507 in diastereotomies in infancy as cause of urinary retention, (testal obstruction, and edema of lower extremities, 404 hormonal conditions in myoma of and genesis of menstrual disturbances in myomatous women, 405 acute torsion of fibroid, 497
- Vagina.** Series of 40 cases of vesicovaginal fistula, 125
- Vagotomy** for gastroduodenal ulcer 291
- Vasospasm.** Traumatic disease, 220
- Vater's ampulla.** Resection of duodenum and head of pancreas for primary carcinoma of head of pancreas and, 127
- Vena.** Large anomalous, (left vena cava) encountered in operation for ligation of patent ductus arteriosus, 95 intravenous nutrition, 110 thrombophlebitis of cubital, in blood donors, 151 ligation of inferior vena cava for prevention of pulmonary embolism 153 entrance of pantopne into, during angiography 231 surgical treatment of long standing deep phlebitis of leg: supplementary report, 416 observations on technique of phlebography 58
- Verrucae viride.** Seven year review of ectoplasia with special reference to treatment 114, 27
- Virus.** Experimental transmission of lymphogranuloma venereum, through placenta, 40
- Vision.** Localized 1/2 inch of temporal crescent defects in focal fields
- Vitamins.** Treatment of nonunion or delayed union of fractures by means of massive oral grafts fixed 11 screws of 5, use of tubes of in strictures and absence of common bile duct 210 technique of using tubes of in establishing portacaval shunts for portal hypertension, 137
- Vitamins.** Effect on infant mortality of administered during labor, 16 abuse of plasma vitamin A determinations in differential diagnosis of fambric preliminary report 130 importance of ascorbic acid (vitamin C) in chest surgery 171 vitamin C and lactational mastitis, 221 Burma collective review 443
- Voice.** Stripping of vocal cords, 45
- Virus.** Tuberculosis of and cerebra contribution to medical statistics of Brazil, 406 several gland tumors of benign (hidradenoma) and malignant (adenocarcinoma) 477
- WAR.** Experiences with injuries and diseases of bone in World War II 46 repair of surgery of compound battle fracture 79 in Mediterranean theater of operations, 50 epidemiology of acute polyomyelitis in India Command, 55 gas gangrene study of 90 cases in evacuation hospital, 68 medical problems of South-east Asia Command, 79 combined injuries of thorax and abdomen, 70 management of intrathoracic and thoracoabdominal wounds in combat zone, 80 compound, comminuted skull fractures produced by missiles, 80 effects of gun blasts on hearing 90 frequency of gastric and duodenal ulcers in Sweden during 1941 surgical management of colon and rectal injuries in forward areas, 117 management of injuries of extra peritoneal rectum in 18 mechanism of wound, 137 mechanics of blast injuries, 157; experiences in prophylaxis and treatment of clostridial infections in casualties from invasion of Europe 155 gas gangrene 53 cases, 114 death, treated at forward general hospital in Italy 58 otolaryngology in Army 151 peripheral nerve injuries 181 review of patients with intrathoracic disease and injury treated on surgical service of U.S. Army General Hospital in North Africa, 58, thoracoabdominal injuries, 11 renal disease in A.I. regional station hospital, 222 abdominal wound in field, 43 anesthesia for men wounded in battle 245, ocular manifestations of malnutrition in released prisoners of, from Thailand, 205 use and control of thoracic surgical teams of auxiliary surgical group, 284, surgery of colon in forward battle area, 296 resuscitation of severely wounded casualties, 315 bacteriology of wounds of in Pacific area, 358

VACCINATION during pregnancy as prophylaxis against postpartal infections, 507

SUBJECT INDEX

- anesthesia in maxillofacial surgical unit with British
 liberation army 341 penetrating cranial wounds
 summary of methods used in management collective
 review 353, methods of accelerating dark adaptation
 and improving night vision 381 injuries of eyes and
 visual pathways, 382 wounds and injuries involving
 paranasal sinuses, 385 observations on definitive treat-
 ment of maxillofacial injuries, 385 abdominal surgery
 in evacuation hospital, 402 intravenous anesthesia in
 tropics, 431 infectious hepatitis, with especial refer-
 ence to occurrence in wounded men 439 problem of
 hemolytic streptococcus carriers in hospital personnel,
 439 burns collective review 443 early treatment of
 open head wounds, 483 thoracoabdominal wounds in,
 487 forward abdominal surgery 495 repair of com-
 plete tear of membranous urethra case report and
 suggested technique for operation 507 pain in men
 wounded in battle 522 military aspects of early
 analgesia and anesthesia, 522 study of shock in battle
 casualties, 533
- Weight, Diet regulation and controlled, in pregnancy 408
 Whipple operation, Method of implanting pancreatic duct
 into jejunum in for carcinoma of pancreas, 401
- Wounding Mechanism of 357
- Wounds, Management of Intrathoracic and thoracoab-
 dominal, in combat zone, 80 mechanics of blast
 injuries, 157 occurrence of bacillus histolyticus in
 accidental without recognized specific infection, 169
- through and through bullet, of mediastinum with re-
 covery 196 immediate care of of thorax, 197 secon-
 dary hemorrhage arising from gunshot, of peripheral
 blood vessels, 234 skin bacteria their role in con-
 tamination and infection of 240 abdominal in field,
 243 infection of 244, anesthesia for men with in
 battle 245 resuscitation of casualties with severe
 335 contiguous skin flaps for of extremities, 336 early
 treatment of of knee joint, 337 secondary infection
 of 337 bacteriology of war in Pacific area, 338 local
 chemotherapy with primary closure of septic, by
 means of drainage and irrigation cannulae 339 pene-
 trating cranial summary of methods used in manage-
 ment collective review 353 war and injuries involv-
 ing paranasal sinuses, 385 early treatment of open
 head, 483 thoracoabdominal, in war, 487 prevention
 and treatment of delayed healing of and ulcerated
 cystitis following surgery for tuberculosis of genito-
 urinary tract, 509 role of chemotherapy in and sur-
 gical infections, 519 use of tantalum oxide type 400,
 in treatment of 521 pain in men with, received in
 battle, 522
- Wrist, Fracture of carpal scaphoid 146 chronic tubercu-
 lar synovitis of 510
- XANTHORUBIN Occurrence in human serum of yell-
 ow substances different from bilirubin and
 carotenoids, 397
